

MICROMORPHOLOGY AND SYSTEMATIC DISTRIBUTION OF PIT MEMBRANE THICKENINGS IN OLEACEAE: TORI AND PSEUDO-TORI

David Rabaey¹, Suzy Huysmans¹, Frederic Lens¹, Erik Smets^{1,2} and
Steven Jansen³

SUMMARY

Recent studies on the functional significance of pit membranes in water conducting cells have renewed general interest in their micromorphology. At least two types of pit membrane thickenings have been described in angiosperm families, *i.e.* genuine tori and pseudo-tori. This study explores the distribution and morphology of pit membrane thickenings in 69 species and 23 genera within Oleaceae using light and electron microscopy. Torus-bearing pit membranes are confirmed for *Osmanthus*, and new records are reported for *Chionanthus retusa*, *Picconia azorica*, and *P. excelsa*, but not for the other species studied of *Chionanthus*. This infrageneric variation suggests that tori represent a plastic feature that has evolved more than once within the family as the result of functional adaptation to efficient and safe water transport. Pseudo-tori are observed in species of *Abeliophyllum*, *Fontanesia*, *Forsythia*, *Jasminum*, *Ligustrum*, *Menodora*, and *Syringa*. Based on structural differences, we state that tori and pseudo-tori can be distinguished as non-homologous features.

Key words: Electron microscopy, pit aperture, pit membrane, plasmodesmata, pseudo-torus, torus, tracheid, vessel element.

INTRODUCTION

Recently, the interest in pit morphology has been renewed by physiological experiments that illustrate the importance of pit membranes in the hydraulic system of plants (Choat *et al.* 2003, 2004, 2006, 2008; Pitterman *et al.* 2005; Wheeler *et al.* 2005). Most angiosperm pit membranes possess a homogeneous pit membrane, while the majority of conifer pit membranes show a central thickening or ‘torus’ surrounded by a highly porous margo. Pit membrane pores in angiosperms are usually very small, with the average pore diameter around 5 nm, although the maximum pore diameter may reach more than 100 nm (Choat *et al.* 2003, 2004, 2008; Sano 2005). Conifers, however, are known to show pore sizes commonly up to 200 nm in diameter (Liese & Johann 1954). Although these differences hold true for most of the angiosperms and gymnosperms,

2) National Herbarium of the Netherlands, Leiden University branch, P.O. Box 9514, 2300 RA Leiden, The Netherlands.

3) Jodrell Laboratory, Royal Botanic Gardens, Kew, TW9 3DS, Richmond, Surrey, United Kingdom.

there seems to be considerably more variation in pit membrane morphology than generally assumed. Recent studies on the morphology of pits revealed a large structural variation, especially with respect to pore size, pit membrane thickness, and presence of a pit membrane ‘thickening’ (Dute *et al.* 2001, 2004; Jansen *et al.* 2004a, b; Sano 2005; Rabaey *et al.* 2006; Sano & Jansen 2006; Jansen pers. comm.). Since pit membranes are responsible for more than 50% of total xylem hydraulic resistance and strongly influence vulnerability to embolism, it is expected that modifications of the pit membrane structure are correlated with trade-offs between efficiency and safety of water transport (Choat *et al.* 2004, 2006; Pitterman *et al.* 2005).

The first report of a non-homogeneous pit membrane in angiosperms included the description of a torus-margo configuration in *Daphne* (Thymelaeaceae) and *Osmanthus* (Oleaceae) (Ohtani & Ishida 1978). Since then, tori have been found in representatives of Cannabaceae, Rosaceae, and Ulmaceae (Wheeler 1983; Dute & Rushing 1990; Dute *et al.* 1992, 2001, 2004; Jansen *et al.* 2004a, 2007). A second type of pit membrane thickening in angiosperms was first found in *Ribes sanguineum* (Grossulariaceae) by Parameswaran and Liese (1973), who described anomalous, pad-like structures associated with pit membranes of fibre-tracheids. Similar thickenings have been found in Elaeagnaceae, Ericaceae, Oleaceae, Rhamnaceae, and Rosaceae, and transmission electron microscopic observations (TEM) illustrated that this type of thickening is associated with plasmodesmata (Parameswaran & Vidal Gomes 1981; Barnett 1982, 1987a, b; Lachaud & Maurousset 1996; Rabaey *et al.* 2006; Jansen *et al.* 2007). Because this feature looks similar to a genuine torus when using light microscopy (LM), the term pseudo-torus was introduced (Rabaey *et al.* 2006).

Oleaceae constitute an interesting angiosperm family to study pit membrane thickenings, because the family includes not only records of tori in *Osmanthus*, but also thickenings reported in *Ligustrum* that look very similar to pseudo-tori (Parameswaran & Vidal Gomes 1981). It is likely that additional records of tori can be found in Oleaceae because their presence has simply been overlooked in previous studies. Indeed, tori seem to be associated with other wood anatomical characters that occur in this family, for instance helical thickenings, round apertures, vasicentric tracheids, and ring-porosity (Baas *et al.* 1988; Jansen *et al.* 2004a). This paper aims to investigate the distribution and morphology of pit membrane thickenings in Oleaceae. Light and electron microscopy of a wide range of genera will help us to determine whether or not pseudo-tori occur in Oleaceae, and how often pit membrane thickenings have evolved within this family.

MATERIAL AND METHODS

A total number of 84 Oleaceae specimens out of 23 genera was studied using LM and scanning electron microscopy (SEM). TEM was used to investigate the ultrastructure of pit membranes in *Chionanthus retusa*, *Ligustrum devalayanum*, and *L. obtusifolium*.

For LM and SEM wood samples were used from the Kew herbarium (K), the wood collection of Kew (Kw), the living collections of the Royal Botanic Gardens, Kew (RBG, Kew), the wood collection of Tervuren (Tw), and the herbarium (BR) and living collections of the National Botanic Garden of Belgium. For TEM, young stem

segments were collected from the living collections of the National Botanic Garden of Belgium. The nomenclature of all species follows the International Plant Names Index (<http://www.ipni.org>). The following species were investigated with reference to their origin and collectors:

Abeliophyllum distichum Nakai: U.K. (RBG, Kew; 2002-411) — *Chionanthus africanus* Welw. ex Gilg & G.Schellenb.: Democratic Republic Congo, J. Lejoly 96/970 (BR); *C. battiscombei* (Hutch.) Stearn: Democratic Republic Congo, F. Malaisse 13022 (BR); *C. compacta* Sw.: French Antilles, Guadeloupe, Ducos (Tw 50116); *C. curvicaulus* Kiew: Brunei (Kw 74848); *C. laxiflora* Blume: Brunei (Kw 74366); *C. pachyphyllus* (Merr.) Kiew: Brunei (Kw 74568); *C. pluriflorus* (Knobl.) Kiew: Brunei (Kw 74825); *C. ramiflorus* Roxb.: India, R.F. Holmacher (BR); *C. retusa* Paxt.: New York, Mori & Gracie 23042 (K); Belgium (living collection BR; 19921859-96); *C. virginica* L.: Belgium (living collection BR; 19380694) — *Comoranthus* sp.: Madagascar, Itamboro, P.B. Phillipson 2751 (BR); *C. minor* H.Perrier: Madagascar, R. Capuron et F. Chauvert 20.785 SF (BR) — *Fontanesia fortunei* Carrière: U.K. (RBG, Kew; 1979-6639); *F. phillyraeoides* Labill.: U.K. (RBG, Kew; 1979-6639) — *Forestiera acuminata* Poir.: USA, Arkansas, H. Nogle (Tw 18323); *F. neo-mexicana* A.Gray: U.K. (RBG, Kew; 1982-2697) — *Forsythia* × *intermedia* Zabel: U.K. (RBG, Kew; 1973-17767); *F. suspense* Vahl: Belgium, Brabant, R. Deschamps (Tw 26308) — *Fraxinus excelsior* L.: Belgium, D. Rabaey — *Haenianthus salicifolius* Griseb.: Puerto Rico, Cerro La Santa, Carite Forest, 3000 m, R.A. Hovard 16833 (BR) — *Jasminum dichotomum* Vahl: Angola, Malanje, R. Deschamps (Tw 28566); *J. fruticans* L.: France, Ardeche, R. Deschamps (Tw 47175); *J. humile* L.: U.K. (RBG, Kew; 1972-2110) — *Ligustrum* sp.: Malaysia, Malaya (Kw 22893); *L. sp.*: U.K. (RBG, Kew; 1991-2307); *L. amurense* Carrière: USA, Texas, H. Nogle (Tw 18326); *L. compactum* Hook. f. & Thomson ex Decne.: India, Jaunsar (Kw 22891); *L. devalayanum* Har.: U.K. (RBG, Kew; 1988-8484); Belgium (living collection BR; 10002001); *L. foliosum* Nakai: U.K. (RBG, Kew; 1989-8337); *L. ibolium* Coe ex Rehder: U.K. (RBG, Kew; 1973-211136); *L. ibota* Siebold: USA, Louisiana, A.N. Green (Tw 36083); *L. ionandrum* Diels: U.K., Kew (Kw 12726); *L. japonicum* Thunb.: USA, Texas (Kw 12727); *L. lucidum* W.T. Aiton: U.K. (RBG, Kew; 161-7906680); Belgium (living collection BR; 19761007); *L. microcarpum* Kaneh. & Sasaki: U.K. (RBG, Kew; 2002-1979); *L. obtusifolium* Siebold: U.K. (RBG, Kew; 1978-6464); Belgium (living collection BR; 19811711); *L. ovalifolium* Hassk.: U.K. (Kw 71687); U.K. (RBG, Kew; 1982-6144); *L. pacificum* Nakai: Japan, Gov. Light microscopy

All wood samples were investigated using light microscopy. Preparation of the wood samples was according to standard techniques as described in Jansen *et al.* (1998). Thin sections (10–15 µm) were prepared using a sliding microtome (Reichert, Vienna, Austria). A mixture of safranin and alcian blue (35 : 65, v/v) was used as staining solution. After staining, sections were washed with distilled water, dehydrated with ethanol and treated with clearing agent Parasolve (Prosan, Merelbeke, Belgium). The sections were embedded in Euparal (Agar Scientific Ltd, Essex, UK). LM-observations were carried out with a Dialux 20 (Leitz, Wetzlar, Germany) fitted with an oil immersion objective. Digital images were made with a PixeLINK PL-B622CF camera.

Scanning electron microscopy

Small blocks (± 3 mm thick) were cut and attached to stubs using electron-conductive carbon paste. The samples were sputter coated for 3 min either with gold (Spi-Supplies, West Chester, Pennsylvania, USA) or with platinum using an EMITECH K550 sputter coater (Emitech Ltd., Ashford, U.K.). Observations were carried out at the Laboratory of Plant Systematics (K.U. Leuven) with a Jeol JSM 6360 SEM (Jeol Ltd., Tokyo, Japan) at 15 kV and with a Hitachi S-4700 field-emission SEM (Hitachi High Technologies Corp., Tokyo, Japan) at 2 kV at the Jodrell Laboratory (RBG, Kew).

Transmission electron microscopy

TEM observations were made on *Chionanthus retusa*, *Ligustrum devalayanum* and *L. obtusifolium*. Fresh wood samples from one- to two-year-old branches were col-

lected at BR. Small segments from thin branches were cut into 2 mm³ pieces and fixed overnight in 2% glutaraldehyde at pH 7.4, buffered with 0.05 M sodium cacodylate at room temperature. After washing in 0.05 M sodium cacodylate buffer, the specimens were postfixed in 1% buffered osmium tetroxide for 4 hours at room temperature, washed, and dehydrated through a graded ethanol series. The ethanol was gradually replaced with LR-White resin (London Resin Co, Reading, U.K.) over several days. The resin was polymerized at 60 °C for 24 hours. Embedded samples were trimmed and sectioned with an ultramicrotome (Ultracut E, Reichert-Jung, Austria). Semi-thin sections cut with a glass knife were heat-fixed to glass slides, stained with 0.5% toluidine blue in 0.1 M phosphate buffer and mounted in DPX (Agar Scientific, Stansted, UK). Ultra-thin sections (± 90 nm) were cut using a diamond knife. The sections were attached to Formvar coated grids and stained with uranyl acetate and lead citrate using a LKB 2168 Ultrastainer (LKB-Produkter AB, Bromma, Sweden). Observations were carried out using a Zeiss EM 900 microscope at 80 kV accelerating voltage.

Terminology follows the IAWA Committee (1989). Quantitative characters were measured using Carnoy 2.1 (Schols *et al.* 2002) and were based on 25 counts for each character.

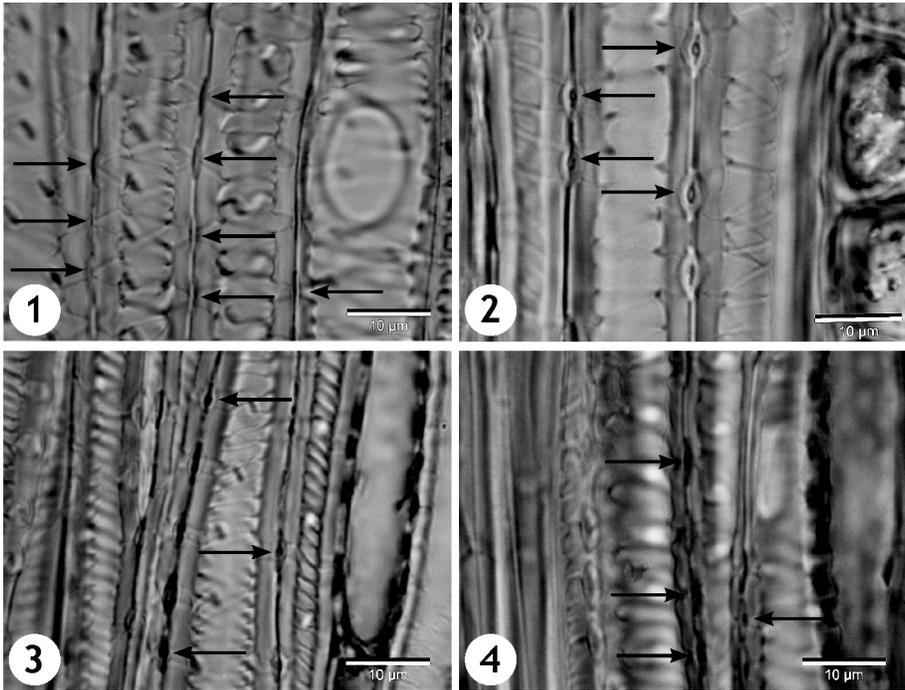

RESULTS

Distribution of pit membrane thickenings

The presence of pit membrane thickenings can be easily overlooked by LM. Even when using a 100 \times oil-immersion objective on thin sections stained with safranin and alcian blue, it is difficult to discern thickenings and to determine their true nature. Nonetheless, pit membrane thickenings are found in 30 species studied (Table 1). However, most of the genera have homogeneous pit membranes: *Comoranthus*, *Forestiera*, *Fraxinus*, *Haenianthus*, *Myxopyrum*, *Nestegis*, *Noronhia*, *Notelaea*, *Nyctanthes*, *Olea*, *Phillyrea*, *Priogymnanthus*, and *Schrebera* (Fig. 1, 5). Pit membrane thickenings appear most commonly in bordered pits of small tracheary elements (Fig. 2, 3). Their

distribution does not show any difference between latewood and earlywood, or between tangential and radial walls. Pits in vessel elements $> 20 \mu\text{m}$ in tangential diameter seem to lack thickenings.

Most of the thickenings associated with pit membranes have a brownish, sometimes transparent, appearance, and a rounded to cap-like structure under LM (Fig. 2, 3). The distribution of these pseudo-tori is inconsistent, *i.e.* not all bordered pits of a particular cell type show pit membrane thickenings. In addition, the thickenings appear in various cell types. Occasionally, more than one thickening was present on a single pit membrane. The cells associated with these pit membrane thickenings show only sporadically helical thickenings and have oval to slit-like outer pit apertures.

Thickenings found in *Chionanthus retusa*, *Osmanthus fragrans*, *Picconia azorica*, and *P. excelsa*, however, differ from those found in the other Oleaceae species studied (Fig. 4). They appear as blue-stained, lens-shaped structures, and are associated with all pits within vascentric tracheids and narrow vessels. The small tracheary elements in species with this type of pit membrane thickening show helical thickenings and inner pit apertures are circular to oval in outline with mean circularity ratios from $0.41 \mu\text{m}$ in *P. azorica* to $0.66 \mu\text{m}$ in *C. retusa* (Table 2). Tori are often associated with the presence of helical thickenings and round pit apertures.

Morphology of pit membrane thickenings

Using SEM observations, a more profound morphological difference can be seen between pseudo-tori (Fig. 6–8), and genuine tori (Fig. 9–12). Species with pseudo-tori show pit membranes with and without thickenings within the same cell (Fig. 7). The density and size of these pseudo-tori differ significantly within a single species (Fig. 8). Most of these thickenings have the following characteristics: 1) a composition of several cores, 2) an irregular outline (Fig. 6, 7), and 3) an eccentric location on the pit membrane (Fig. 6–8). Microfibrils in the pit membrane are randomly to radially distributed. Genuine tori, which were observed in our sampling in *Chionanthus*, *Osmanthus*, and

Detail of half-bordered pits of tracheid (T)-parenchyma (P) showing a pit membrane with a pseudo-torus at the tracheid side. A protective layer (PL) is present at the side of the parenchyma.

Picconia, show a round to oval structure with a mean circularity ratio between 0.80 and 0.85 (Table 2). The torus diameter is wider than the aperture for (Fig. 13), with the mean horizontal diameter of the torus varying from 1.00 to 2.18 μm in *P. azorica* and *P. excelsa*, respectively. The mean horizontal axis of the outer pit aperture varies between 0.58 and 1.00 μm (Table 2). This is very clear for *C. retusa*, *O. fragrans* and *P. excelsa*. The tori present in *P. azorica* are remarkably small compared with the former three (Table 2). Tori are consistently associated with all pits in a single cell (Fig. 11). Tori are sometimes oval (Fig. 10), reflecting the outline of the inner pit aperture. The microfibrils of the margo show a radial orientation.

Ultrastructure of pit membrane thickenings (TEM)

A central torus, which is observed in *Chionanthus retusa*, is usually visible on both sides of a pit pair and is more electron-dense than the remainder of the pit membrane. Tori are wider than the outer pit apertures. The margo has a similar appearance as homogeneous pit membranes in vessel elements (Fig. 13). A pit membrane annulus occurs in both homogeneous and torus-bearing pit membranes (Fig. 10, 14). A thin electron-dense coating is visible on the pit chamber, the torus, and the inner secondary cell wall (Fig. 14).

The structure of pseudo-tori found in the two *Ligustrum* species studied, is shown in Figures 15–18. Two developmental stages of pseudo-tori can be distinguished: 1) “young” pseudo-tori with a solid structure, which usually show plasmodesmata directed to the centre of the thickening (Fig. 17), and 2) fully developed pseudo-tori consisting of an electron dense cap-like layer overlaying a transparent area and showing remnants of plasmodesmata (Fig. 15, 16). The cap-like structure of a young pseudo-torus becomes more electron-dense after hydrolysis, while enzymes remove part of the underlying pit membrane thickening, resulting in a hollow and transparent appearance. No differences were observed in cell development or timing of the developmental stages between cells with or without pseudo-tori. Pseudo-tori are only found in some pit membranes of tracheary elements (Fig. 16). We observed also pseudo-tori in half-bordered pits of tracheid-parenchyma or vessel-parenchyma pit pairs, but then only at the tracheary element side (Fig. 18). In that case, a protective layer occurs at the side of the parenchyma cell.

DISCUSSION

Oleaceae with torus-bearing pit membranes

Two types of pit membrane thickenings are present in Oleaceae. The first type, which we only observed in *Osmanthus fragrans*, *Picconia azorica*, *P. excelsa*, and *Chionanthus retusa*, is interpreted as a genuine torus with a more or less circular thickening that is centrally located on every pit membrane in the same cell. In addition to previous reports of tori in various species of *Osmanthus* (Ohtani & Ishida 1978; Dute & Rushing 1987), the present study demonstrates new records in the genera *Picconia* and *Chionanthus*. The wood anatomical characters associated with tori, such as helical thickenings, circular to oval pit apertures, tracheids, and dendritic vessel arrangement occur in these three species and were also reported by earlier studies (Patel 1978; Baas *et al.* 1988).

Although all torus-bearing species seem to belong to Group V of Baas *et al.* (1988), the presence of this set of wood anatomical features does not seem to be an absolute prerequisite for the occurrence of tori, because genera such as *Nestegis*, *Notelaea*, and *Phillyrea* show a similar wood anatomy but do not have tori in the species studied. Although some *Olea* species also belong to Group V, we were unable to test whether tori occur in these *Olea* species due to lack of material.

In some genera, the distribution of tori shows interesting variation at species level. As previously suggested for species within *Ulmus* and related Ulmaceae, tori are more common in temperate climates than in tropical environments (Dute *et al.* 2004; Jansen *et al.* 2004). Thus, the ecological and geographical distribution of species within a genus could have influenced the development of a torus. *Osmanthus*, for instance, includes about 30 species of evergreen plants, mostly native to warm temperate Asia with a distribution from the Caucasus to Japan, although some species also grow in tropical East Asia and one in the USA. Several authors reported the presence of tori in *Osmanthus* and, as far as we know, all species studied in this genus have tori on the pit membranes of vasicentric tracheids and vessel elements (Ohtani & Ishida 1978; Dute & Rushing 1987, 1988). It is unclear, however, whether tori characterize this genus entirely. As for the genus *Chionanthus*, only two out of the ten species examined in this study show a distribution in temperate areas, namely *C. retusa* and *C. virginica*, whereas the other species show a tropical distribution and were treated in the past as *Linociera* (Stearn 1976). Interestingly, tori were found in *C. retusa*, which is native to China, Korea and Japan, but not in *C. virginica*, which is a tree from North-East

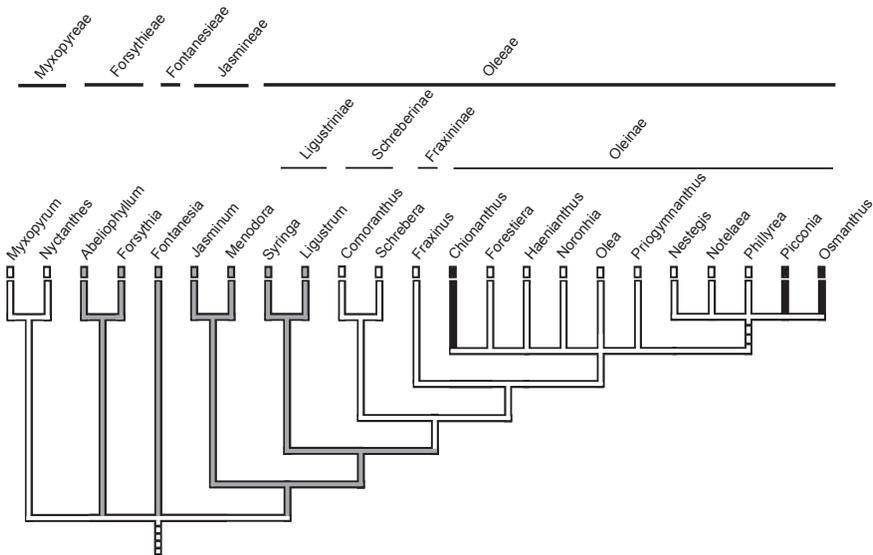

Figure 19. Simplified phylogenetic hypothesis of the Oleaceae based on Wallander & Albert (2000). Tori-bearing taxa are indicated in black, pseudo-tori-bearing taxa in gray and species with homogeneous pit membranes in white.

America. It would be interesting to study additional material of *C. virginica* since the absence of tori in the specimen investigated does not support the general idea that tori are inherited as a functional character complex in temperate areas with a seasonally dry period (Jansen *et al.* 2004). Tori are present in both species of *Picconia*, which were previously included in *Notelaea* (Johnson 1957; Green 1968). The distribution of *Picconia* is restricted to the islands of the Macaronesian archipelago, while all *Notelaea* species occur in East Australia. At species level tori seem to be consistently present in every specimen of the same species. Tori are observed in two specimens of *C. retusa* and *P. excelsa* and our observations of torus-bearing pits in *O. fragrans* and *P. azorica* confirm observations of respectively Ohtani and Ishida (1978) and Dute *et al.* (2008).

According to our results, it seems plausible to assume that tori have developed more than once during the evolution of Oleaceae, with probably one origin of tori in *Chionanthus*, and at least one in *Osmanthus* and *Picconia* (Fig. 19) (Wallander & Albert 2000; Lee *et al.* 2007). Dute *et al.* (1988, 1990) and Coleman *et al.* (2004) demonstrated that tori in *Osmanthus* are formed during late developmental stages and become consequently lignified. It would be interesting to know whether tori in *Chionanthus* are similar to those of *Osmanthus* in terms of their development and chemical composition. The safranin-alcian blue staining used in this study does not show any differences between these genera. Dute *et al.* (2008) suggested that tori in *Picconia* and *Osmanthus* are similar in chemistry based on a similar stain distribution after treatment with KMnO_4 .

Pseudo-tori in Oleaceae

The pit membrane thickenings found in 26 Oleaceae species are similar to the pit membrane thickenings reported by Parameswaran and Vidal Gomes (1981) in *Ligustrum lucidum* and represent pseudo-tori. Characteristic features of pseudo-tori include their irregular distribution, a hollow structure under an electron-dense cap, an asymmetrical outline, and frequently an eccentric location on the pit membrane. The pseudo-tori-bearing species fall within Group I and II *sensu* Baas *et al.* (1988) that are characterized by solitary vessels and fibre-tracheids. The reason why pseudo-tori seem to be restricted to Group I and II is most likely due to a fairly strong correlation between pseudo-tori and fibre-tracheids. One exception can be found, however. *Myxopyrum ovatum* and *M. nervosum* show fibre-tracheids but no pseudo-tori in the material examined in this study. Further sampling is necessary since we only studied two species of *Myxopyrum*.

Our observations of pseudo-tori in seven genera of Oleaceae seem to support the idea that pseudo-tori are quite common among angiosperms, as was also suggested by previous studies on Ericaceae and Rosales (Rabaey *et al.* 2006; Jansen *et al.* 2007). Detailed wood anatomical studies on Oleaceae and Ericaceae did not comment on the distribution of pseudo-tori (Baas *et al.* 1988; Lens *et al.* 2004a, b). This is most likely because pit membrane thickenings are very small and easily overlooked. Relatively thin sections (10–15 μm) and the use of a 100 \times immersion oil-objective are generally required for their detection when using a light microscope.

There is no obvious link between the presence of pseudo-tori and ecological aspects such as growth form, and a deciduous or evergreen habitat. Furthermore, it is doubtful

whether pseudo-tori show any clear systematic significance. Their distribution can be variable within a genus, as is illustrated for instance in species of *Forsythia*, *Jasminum*, and *Ligustrum*. Nevertheless, the distribution of pseudo-tori within Oleaceae may suggest that it is a primitive feature with a distribution in the Fontanesieae, Forsythieae, Jasmineae, and the Ligustrinae clade of the tribe Oleaeae according to Wallander and Albert (2000) (Fig. 19). Although this topology has several unresolved clades, Ligustrinae take a sister position to the remaining clades of Oleaeae. Myxopyreae are sister to the other Oleaceae genera in Lee *et al.* (2007). Due to a smaller sampling in that study, no clear conclusions can be made. Although there are clear ultrastructural similarities between the pseudo-tori observed in Oleaceae and other angiosperm families, it would be useful to obtain more details about their chemical composition and development. To date, developmental data of pseudo-tori are limited to one *Pyrus* species and two *Sorbus* species (Barnett 1987a, b; Lachaud & Maurousset 1996).

Functional aspects

The function of tori in pit membranes of gymnosperms has received much attention and is fairly well understood (Bailey 1913; Pittermann *et al.* 2005). Similar ideas about the role of tori in angiosperms have been suggested: tori could offer narrow tracheary elements the functional advantage of a higher resistance to cavitation and thus may provide an extra safety against air-seeding (Wheeler 1983; Dute *et al.* 1990, 2001; Carlquist 1996; Jansen *et al.* 2004, 2007). Narrow tracheary elements with torus-bearing pits in the latewood of elm species have been illustrated to be very resistant to embolism formation (Ellmore & Ewers 1985; SJ, unpubl. data). However, experimental evidence demonstrating the potentially higher hydraulic resistance and air-seeding thresholds of pit membranes with tori is still missing.

It is more difficult to speculate on the possible function of pseudo-tori. In any case, pseudo-tori have most likely not the same purpose as tori, because pseudo-tori do not take a central position on the pit membrane, have a highly variable structure, and are inconsistently present within a cell. The most obvious function could be related to the presence of abundant plasmodesmata, which allow intercellular communication and transport of water, nutrients, and other molecules (Epel 1994; Haywood *et al.* 2002; Roberts & Oparka 2003). A possible function was suggested by Barnett (1987a), who stated that the thickenings may play a role in cell differentiation since the cap-like thickenings could prevent or delay passage of autolytic enzymes. This was contradicted by Lachaud and Maurousset (1996), who observed plasmodesmata crossing the cap. As far as we know, no developmental differences have been observed between fibre-tracheids with or without pseudo-tori.

CONCLUSION

Pit membrane thickenings are much more abundant than previously assumed. Two morphologically distinct types can be easily distinguished in Oleaceae. New records of tori in *Chionanthus retusa* and the two *Picconia* species are presented and the presence of tori is confirmed for *Osmanthus fragrans*. Pseudo-tori are observed in several spe-

cies of *Abeliophyllum*, *Fontanesia*, *Forsythia*, *Jasminum*, *Ligustrum*, *Menodora*, and *Syringa*. The inconsistent distribution of tori and pseudo-tori, even within one genus, suggests the plastic and non-homologous nature of pit membrane thickenings. More ultrastructural work and physiological experiments on pseudo-torus-bearing species are necessary to clarify the function and homology of pseudo-tori.

ACKNOWLEDGEMENTS

We thank Dr. Roland Dute (Auburn University, USA) for useful suggestions and discussion on tori in Oleaceae and Annelies Pletzers (Royal Botanic Gardens, Kew) for assistance with the preparation of samples for SEM and TEM. Prof. J. Rammeloo from the National Botanic Garden of Belgium and Dr. H. Beeckman from the Royal Museum for Central Africa are acknowledged for the supply of wood samples. We thank SYNTHESYS for financial support to DR (GB-TAF-3115). Research at the Laboratory of Plant Systematics is supported by research grants from the K.U. Leuven (OT/05/35) and the Fund for Scientific Research-Flanders (Belgium) (G.0268.04 and G.0250.05). FL is a postdoctoral fellow of the Fund for Scientific Research-Flanders (Belgium). Financial support to SJ was provided by a research grant from the Royal Society (2006/R1) and NERC (NE/E001122/1).
