Introduction

'I find to my great surprise that a ship is singularly comfortable for all sorts of work. Everything is so close at hand, and being cramped makes one so methodical, that in the end I have been a gainer. I already have got to look at going to sea as a regular quiet place, like going back to home after staying away from it. In short, I find a ship a very comfortable house, with everything you want, and if it was not for sea-sickness the whole world would be sailors.'

Charles Darwin in a letter to his father during the voyage of the *Beagle*, 1832.
Published in *The life and letters of Charles Darwin*
(edited by his son Francis Darwin, 1887).

In his famous book *The Voyage of the Beagle*, Charles Darwin writes about his adventures and discoveries while sailing across the world's oceans. For centuries, mankind has been wondering what is out there in the seas, and even now, almost 2 centuries after the voyage of the *Beagle*, this question is still awaiting numerous answers from the deep. The magnitude of global marine species diversity has been estimated at 0.7-1.0 million (Appeltans et al., 2012). Of this number, approximately 229,000 species have been described, of which the Animalia constitute approximately 196,000 species (World Register of Marine Species, WoRMS). Marine species are not distributed homogeneously throughout the global ocean, but their distributions are directly or indirectly linked to oceanographic properties like temperature, salinity, and chlorophyll concentration (Van der Spoel and Heyman, 1983; Longhurst, 1998; Norris, 2000; Reygondeau et al., 2013). These properties enable the division of all oceans into biogeochemical provinces that provide a diverse range of ecological niches as well as barriers to dispersal for pelagic species, amongst which the zooplankton (FIGURE 1; De Vargas et al., 2015; Boltovskoy and Correa, 2016, 2017). Unlike earlier episodes of change throughout the geological time scale, current ocean change is partially caused by human activity. To track the effects of ocean change on zooplankton species diversity, distribution, and across trophic levels, it is essential to gain insights into when current biodiversity evolved, what part of the marine biodiversity is where, and how closely related species can be distinguished.

During 6 weeks in 2014, I was part of an oceanographic expedition from England to the Falkland Islands, hoping to obtain zooplankton samples that would help me address the questions above. Indeed, like Darwin wrote, all utilities were close at hand. The work was methodical and followed a tight schedule. (If you, however, think that being a sailor is the major activity of a modern-day marine biologist, you are wrong: most often they are analyzing data and writing papers or grant proposals). During this expedition, I came to realize the true vastness of the ocean. Oceans cover approximately 71% of the planet's surface. Of the total surface covered by oceans, 46.6% is covered by the Pacific Ocean, followed by the Atlantic (23.5%), Indian (19.5%), Southern (6.1%), and Arctic (4.3%) oceans. The average depth of the ocean has been estimated at 3682 m. Together the oceans contain 97% of the Earth's water (Charette and Smith, 2010).

Twelve animal phyla are prevalent in the marine metazoan holoplankton: Annelida (polychaetes: bristle worms), Arthropoda (predominantly represented by crustaceans: copepods, cladocerans, ostracods, amphipods, mysids, euphausiids), Chaetognatha (arrow worms), Chordata with the subphyla Vertebrata (represented by small fish), Tunicata (salps, pyrosomes, dolioids, appendicularians), and Cephalochordata (lancelets), Cnidaria (amongst which are jellyfish and box jellies), Ctenophora (comb jellies), Mollusca (predominantly represented by the gastropod groups pteropods and heteropods), Nematoda (roundworms), Nemertea (unsegmented, worm-like organisms), Platyhelminthes (flatworms), and Rotifera (wheel animals; Angel, 1993). Arthropoda are consistently the dominant pelagic metazoan group, and most arthropods have been identified as copepods (De Vargas et al., 2015; Pearman and Irigoien, 2015).

In recent years, marine calcifiers have gained considerable attention because of their potential vulnerability to oceanic uptake of carbon dioxide (CO₂; e.g., Drake et al., 2014; Bednaršek et al., 2016; Moya et al., 2016; Hattich et al., 2017; Kroeker et al., 2017; Manno et al., 2017; Riebesell et al., 2017). Major groups of calcifying plankton are pteropods and heteropods with aragonite shells, and coccolithophores and foraminifers with calcite shells (Fabry et al., 2008). Pteropod and heteropod gastropods occur throughout the world's oceans and are especially vulnerable to the effects of ocean acidification because aragonite is more soluble than calcite. However, their use as bioindicators of the effects of ocean acidification is compromised by limited knowledge of their taxonomy and distributions for understanding species-specific responses to ocean change. Accurate insights into their taxonomy,

FIGURE 1. Average distribution of 56 biogeochemical provinces across the global ocean as calculated by Reygondeau et al. (2013) based on the monthly distribution patterns of biogeochemical provinces from January 1998 to December 2007. Edited from Reygondeau et al. (2013), with permission from publisher John Wiley and Sons.

genetic diversity, and biogeography are the essential first steps to predicting the ecological and evolutionary responses of individual species to ocean change.

Atmospheric CO₂ concentrations varied between 180 ppmv during glacials and 280-300 ppmv during interglacials in the last 650,000 years (Siegenthaler et al., 2005). As a consequence of human activity in the past 200 years, the present atmospheric CO₂ concentration is ~410 ppmv (National Oceanic & Atmospheric Administration, 2017) with an expected increase of ~0.5% per year (Forster et al., 2007). Approximately one third of the anthropogenic CO₂ emission is currently stored in the ocean (Sabine et al., 2004). The Southern Ocean will become undersaturated with aragonite and calcite when atmospheric CO₂ concentrations exceed 560 and 900 ppmv, respectively. Given the current rise in atmospheric CO₂ concentrations, it is projected that Southern Ocean surface waters will begin to become undersaturated with respect to aragonite by the year 2050, followed by an extension throughout the entire Southern Ocean, the subpolar Pacific Ocean, and the Arctic Ocean by 2100 (Orr et al., 2005; Comeau et al., 2012). On time scales of several thousands of years, it is estimated that 90% of the anthropogenic CO₂ emissions will end up in the ocean (Sabine et al., 2004). It is expected that pteropods will have difficulty to maintain shells in waters that are undersaturated with respect to aragonite. This may have considerable ecological and biogeochemical impacts, as pteropods serve as food in the diets of a variety of zooplankton and fish species and play a key role in marine calcification.

This thesis aims to understand the diversity, distribution, and evolution of different groups of marine zooplankton in the global ocean. The majority of this thesis (Chapters 2-6) focuses on calcifying zooplankton, more specifically the pelagic gastropods. For instance, I will investigate when current pteropod diversity arose (Chapter 2), how pteropod taxa are related (Chapters 2-5), how species within the pteropod genera *Cuvierina* and *Diacavolinia* can be distinguished and where they occur across the global ocean (Chapters 3-5), and what part of the pteropod and heteropod biodiversity is where in the Atlantic Ocean (Chapter 6). Additionally, Chapter 7 focuses on hyperiid amphipods. They are not marine calcifiers, but are a group of crustaceans that often live as commensals and parasites of gelatinous zooplankton and are an example group of indirect dependence on oceanographic properties. Because hyperiid amphipods were commonly found in zooplankton samples, they allowed for comparison of diversity patterns with pelagic gastropods.

STUDY ORGANISMS

PTEROPODS

Pteropods are a group of holoplanktonic heterobranch gastropods (Jörger et al., 2010). They comprise the orders Thecosomata, commonly referred to as ‘sea butterflies’, and Gymnosomata, referred to as ‘sea angels’ because their two parapodia resemble the shapes of the wings of butterflies or angels (FIGURE 2). According to WoRMS, there are 83 extant thecosome species and 43 gymnosome

FIGURE 2. Representatives of pteropods (not scaled to relative sizes). Euthecosomata photos taken by K.T.C.A. Peijnenburg and E. Goetze during Atlantic Meridional Transect 22 (2012), Pseudothecosomata and Gymnosomata photos taken by K. Osborne and S. Bush (2012 and 2013).

species worldwide, and many fossil species also have been described (Janssen and Peijnenburg, 2014). Most pteropods are between 0.05 and 2 cm in size. Most pteropod species are epipelagic, but some species are meso- or bathypelagic, and they are vertical migrators moving to shallower depths at night (Van der Spoel and Dadon, 1999; Bé and Gilmer, 1977). The thecosomes feed on microplankton by producing mucus webs, whereas gymnosomes are active predators, often feeding on thecosomes (Gilmer and Harbison, 1986; Van der Spoel and Dadon, 1999). The thecosomes are divided into the suborders Euthecosomata (11 genera, 60 species), with aragonite shells throughout their lives, and Pseudothechosomata (five genera, 23 species), with sinistrally coiled shells or a semi-soft pseudoconch and an aragonite shell during the larval stage (Meisenheimer, 1906; Van der Spoel and Dadon, 1999; Janssen, 2012). Of the euthecosomes, the superfamily Cavolinioidea (eight genera, 52 species) has uncoiled shells, and the superfamily Limacinoidea (three genera, eight species) has coiled shells. Gymnosomes have larval shells that are shed during metamorphosis to the adult stage (Lalli and Conover, 1976; Van der Spoel and Dadon, 1999).

HETEROPODS

Heteropods are commonly referred to as ‘sea elephants’ because of their elongate and flexible proboscis and are formally known as Pterotracheoidea (Caenogastropoda). There are three heteropod families: Atlantidae (three genera, 23 species), Carinariidae (three genera, nine species), and Pterotracheidae (two genera, five species; Wall-Palmer et al., 2016a,b,c). The Atlantidae are fully shelled, generally less than 1 cm in size, and are the least efficient swimmers of all heteropods (FIGURE 3). They can retract their bodies into their keeled, dextrally coiled shells (Seapy et al., 2003). *Atlanta* species have shells composed of aragonite, *Protatlanta* has a shell of aragonite and a keel of conchiolin, and *Oxygyrus* has a shell largely composed of conchiolin (Richter and Seapy, 1999). The Carinariidae have very large, cylindrical bodies that are much larger than their shells and can become up to 50 cm long (Lalli and Gilmer, 1989). The Pterotracheidae have an elongated body that

FIGURE 3. Heteropods (Atlantidae). Note the eye and proboscis in the upper part of the image. Photo taken by K.T.C.A. Peijnenburg and E. Goetze.

can reach a length of 33 cm and only have larval shells (Richter and Seapy, 1999). Heteropods occur primarily at tropical and subtropical latitudes, but *Atlanta ariejansseni* is adapted to the specific conditions of the Southern Subtropical Convergence Zone (Richter and Seapy, 1999; Wall-Palmer et al., 2016a). Heteropods occur in upper mesopelagic and epipelagic waters (Richter and Seapy, 1999). They are visual predators that feed on other zooplankton and small fishes, and as juveniles they feed on small zooplankton and phytoplankton (Lalli and Gilmer, 1989; Seapy et al., 2003). The diversity and abundance of heteropods, predominantly Atlantidae, are studied along a 2014 north-south transect in the Atlantic Ocean in Chapter 6.

HYPERIID AMPHIPODS

The amphipod suborder Hyperiidea is an exclusively pelagic group of crustaceans with 292 species currently accepted in WoRMS. Hyperiids are classified into two infraorders, the bathypelagic and mesopelagic Physosomata and the epipelagic and mesopelagic Physocephalata (FIGURE 4; Vinogradov et al., 1996; Browne et al., 2007; Hurt et al., 2013). The Physocephalata are the most diverse group, with approximately 65% of extant species in 20 families. Most diverse hyperiid families are the Scinidae (Physosomata; 45 species) and the Hyperiididae (Physocephalata; 29 species, WoRMS, 2016). Most hyperiid amphipods are parasitoids and commensals of gelatinous zooplankton, i.e., tunicates, medusae, ctenophores, and siphonophores serve as primary hosts (Harbison et al., 1977; Madin and Harbison, 1977; Laval, 1980; Phleger et al., 1999; Gasca and Haddock, 2004). Some families and genera appear to be restricted to particular host groups while others are less selective (Harbison et al., 1977; Madin and Harbison, 1977; Laval, 1980; Lavaniegos and Ohman, 1999; Gasca et al., 2015; Riascos et al., 2015). Free-living hyperiids occur predominantly in polar environments, where they can dominate the total zooplankton biomass and serve as prey for squids, fishes, and seabirds (Bocher et al., 2001; Laptikhovskiy, 2002; Shreeve et al., 2009; Waluda et al., 2010). The diversity and distribution of hyperiids are studied across a 2012 transect in the Atlantic Ocean in Chapter 7.

STUDY METHODS

TIME-CALIBRATED MOLECULAR PHYLOGENIES

Pteropods have an extensive fossil record, primarily consisting of euthecosome shells (e.g., Janssen, 2007, 2012; Janssen and Peijnenburg, 2017). In combination with molecular methods for phylogenetic inference, the fossil record improves our understanding of the evolutionary history of pteropods by providing a framework for ages of taxa. Because pteropod shells are fragile, they do not survive significant transportation and are rarely displaced from one sedimentary unit into another. This makes them reliable fossils for fossil-calibrated phylogenetic and biostratigraphic purposes (Janssen and Peijnenburg, 2014). Vicariance events, or the occurrence of physical barriers to dispersal, have had profound effects on marine evolu-

tion. Examples are the Terminal Tethyan Event separating the Atlantic from the Indian Ocean ~19 million years ago (mya), and the formation of the Isthmus of Panama (IOP) between the Atlantic and Pacific oceans ~3 mya (Harzhauser et al., 2007; Bowen et al., 2016; O’Dea et al., 2016). Vicariance events have caused centers of marine diversity to shift and have reduced connectivity by changes in ocean circulation, but the timing of these effects on specific taxa is not fully understood (e.g., Knowlton and Weigt, 1998; Lessios, 2008; Renema et al., 2008; Bowen et al., 2016; O’Dea et al., 2016). Divergence between lineages from different oceans would allow the use of vicariance events as molecular clock calibrations and their comparison with fossil calibrations. However, refinement of fossil as well as biogeographic calibrations will play an important role in strengthening the reliability of molecular clocks (Ho, 2014). In this thesis, I use fossil records of pteropods to calibrate molecular phylogenies in Chapter 2, providing a framework for ages of genera and superfamilies. Additionally, inferred ages of clades are compared based on different calibration methods.

INTEGRATIVE TAXONOMY AND THE SPECIES CONCEPT

Integrative taxonomy tests species hypotheses using a combination of diverse and sometimes incomplete character and data types. It aims to prevent under- or over-estimation of species numbers by describing species based on congruence between morphological and genetic information, with additional supporting characteristics such as geography, behavior, or ecology (McManus and Katz, 2009; Padial et al., 2010; Smith and Hendricks, 2013; Edwards and Knowles, 2014; Karanovic et al., 2016). Recently, novel tools and technologies have improved the application of integrative taxonomy for species discovery, such as advances in high-throughput DNA sequencing, morphometric methods, geographic information systems, and virtual access to museum collections (Vogler and Monaghan, 2006; Leray and Knowlton, 2016). Although statistically identified genetic lineages play a major role in species detection because they are objective tests of species hypotheses that satisfy multiple species concepts, the sole use of genetic information for species detection may fail to delimit the same number of species compared to integrative taxonomic methods (De Queiroz, 2007; Hausdorf, 2011; Edwards and Knowles, 2014; Morard et al., 2016; Sukumaran and Knowles, 2017). Species may go undetected due to a limited set of genetic markers, because they may be distinct only in other genes, morphology, or ecological niche space (Karanovic et al., 2016). I apply an integrative taxonomic species concept in this thesis to study pteropod diversity by using two or three genetic markers combined with geographic information (Chapters 2-5), and additionally, with geometric morphometric information (Chapters 3-5) and ecological niche models (ENM; Chapter 3).

FIGURE 4. Representatives of the 17 families of hyperiid amphipods that were observed in samples from the Atlantic Meridional Transect 22 (2012). All scale bars represent 1 mm. Edited from Chapter 7.

GEOMETRIC MORPHOMETRICS

Two- or three-dimensional geometric morphometrics is the statistical analysis of shape based on landmark coordinates on a structure (Bookstein, 1991). Shape differences between specimens can be identified by separating shape information from size by Procrustes superimposition, which involves the scaling, translation, and rotation of the landmark coordinates, so that the specimens fit on top of each other in the best possible way. The results can be visualized as actual shapes or shape deformations (Mitteroecker and Gunz, 2009). Landmarks often are point locations that are biologically homologous between species. However, if it is impossible to quantify a shape by homologous landmarks alone, they may be supplemented with smooth curves consisting of semilandmarks that enable quantification of the curve (Gunz and Mitteroecker, 2013). Shelled gastropods have complex and diverse shell shapes that enable detailed geometric morphometric analyses to distinguish species and geographic variation in a powerful way. In this thesis, geometric morphometric methods are applied to multiple orientations of pteropod shells to distinguish between *Cuvierina* species in Chapters 3 and 4 and *Diacavolinia* species in Chapter 5. Geometric morphometric analysis is particularly useful in studies that include historical specimens from, e.g., museum collections for which no genetic information can be obtained (Chapter 5).

ECOLOGICAL NICHE MODELING

Accurately assessing species distribution patterns is essential for predicting species-specific ecological and evolutionary responses to climate change. Ecological niche modelling (ENM), also referred to as Species Distribution Modelling (SDM), is an important tool to analyze and predict the biogeographical distributions of species based on their response to environmental variables. In contrast to the terrestrial domain, ENM has been applied to the marine environment only since the last ~10 years (Elith and Leathwick, 2009; Dambach and Rödder, 2011; Robinson et al., 2011; Bentlage et al., 2013; Beaugrand et al., 2014). Prior to this, studies of biogeography of marine taxa relied on qualitative estimation of species distributions (e.g., Bé and Gilmer, 1977; Van der Spoel and Heyman, 1983). To estimate ecological tolerances of different taxa, ENM combines presence data of species with spatial data layers of environmental data. The use of presence-only data (i.e., without absence data) is preferred, because collection of sampling locations is often spatially biased toward easily accessible areas and, therefore, the apparent lack of observations of a species in a particular area does not necessarily imply that the species does not occur there (Phillips et al., 2009). Techniques have been developed to allow for significance testing of ENMs based on presence-only data (Raes and Ter Steege, 2007). In this thesis, two-dimensional ENM is applied to quantitatively estimate the ecological tolerances of six *Cuvierina* pteropod morphotypes (Chapter 3).

SPECIES DIVERSITY AND DISTRIBUTION PATTERNS

An important source of Atlantic zooplankton samples used throughout this thesis is the Atlantic Meridional Transect (AMT), a multidisciplinary expedition for biolo-

gical, chemical, and physical oceanographic research (FIGURE 5). It is presently an annual transect of >12,000 km between the United Kingdom and the South Atlantic (the Falkland Islands, Chile, or South Africa) and traverses a range of biogeochemical provinces (Rees et al., 2015). For this thesis, I participated in the 2014 expedition and obtained quantitative samples of meso- and macrozooplankton

FIGURE 5. Cruise tracks of AMT1 to AMT25. Transect colors are yellow for AMT1 to 11 (1995-2000), red for AMT12 to AMT17 (2002-2006), blue for AMT18 to 22 (2007-2012), and purple for AMT23 to AMT25 (2012-2015). Ocean colors are from a composite chlorophyll *a* image (courtesy of NEODAAS) for October 2009 (AMT19). From Rees et al. (2015), with permission from publisher John Wiley and Sons.

from the upper ~300 m (AMT24: Chapter 6). I also used non-quantitative zooplankton samples from the upper ~300 m that were collected during the 2012 edition (AMT22: Chapters 2-5 and 7). During both expeditions, samples were obtained by conducting oblique tows at night using a bongo net of 0.71 m diameter and a mesh size of 200 μm (Chapter 6) or 333 μm (Chapter 7).

Biogeochemical provinces of the world's oceans are defined by ecosystem dynamics and biogeochemistry. A total of 56 biogeochemical provinces has been characterized (Longhurst, 1998; Reygondeau et al., 2013). The locations of these biogeochemical provinces are not fixed but fluctuate at seasonal and interannual timescales. It is often assumed that the distributions of distinct species assemblages of marine zooplankton correspond with the distributions of biogeochemical provinces. With the ongoing discovery and collection of marine zooplankton taxa, we gradually obtain a better picture of the biogeographical distributions of pelagic species, and this assumption can be tested by visualization and quantification of similarities in species composition across stations by, e.g., hierarchical clustering, similarity profile analysis, and non-metric multidimensional scaling (Clarke 1993; Clarke and Warwick, 2001; Clarke and Gorley, 2006). Distributions of pelagic species assemblages of pteropods, heteropods, and amphipods are examined in Chapters 6 and 7.

THESIS OUTLINE

This thesis aims to improve current understanding of biogeographical and evolutionary patterns in a selection of zooplankton taxa: pteropods, heteropods, and amphipods. I participated in an expedition across the Atlantic Ocean to collect numerous new specimens in addition to using extensive museum collections from all oceans. I obtained new molecular, geometric morphometric and biogeographic information to better comprehend their diversity, distribution, and evolution in the global ocean.

In Chapter 2, I study the phylogenetic relationships of pteropods based on combined analyses of three genetic markers: Cytochrome Oxidase I (COI) mtDNA, 28S rDNA, and 18S rDNA. With a total of 55 included pteropod species spanning the diversity of the group and sampled from each ocean basin, I include molecular data of seven additional euthecosome, two pseudothecosome, and five gymnosome species relative to prior studies. I reconstruct the evolutionary history of pteropods using a fossil-calibrated molecular clock approach.

In Chapter 3, I aim to understand the biogeography and evolution of *Cuvierina* pteropods from the Atlantic, Pacific, and Indian Ocean as a basis for taxonomic revisions by applying an integrative taxonomic approach to this genus for the first time. Geometric morphometric analyses of shell shape variation, phylogenetic analyses based on COI and 28S, and Ecological Niche Modelling are applied to distinguish between and within extant taxa, determine the temporal sequence of evolution in the genus, and explore the current and past biogeographic context of extant *Cuvierina* species.

In Chapter 4, I revise the taxonomy of *Cuvierina* pteropods based on findings from Chapter 3. I reject the earlier proposed subgenera within *Cuvierina* and describe a new species endemic to the Pacific Ocean, *Cuvierina tsudai*.

In Chapter 5, I apply an integrative taxonomic approach to assess species boundaries in *Diacavolinia* pteropods from the Atlantic, Pacific, and Indian Ocean. I develop a method for identifying species boundaries by combining incomplete and varied datasets, and inferences are based on congruence between geometric morphometric analyses of shell shape, phylogenetic analyses based on COI and 28S, and geographic data. This study includes type specimens that were used to describe *Diacavolinia* species.

In Chapter 6, I assess species distributions, abundances, and biogeographical trends in species diversity, as well as biomass of pteropods along a 2014 transect from 46°N to 46°S in the Atlantic Ocean. To my knowledge, this is the most comprehensive study of the diversity and abundance of holoplanktonic gastropods across the Atlantic Ocean to date.

In Chapter 7, I report on the diversity and distribution of hyperiid amphipods across a 2012 transect in the Atlantic Ocean and examine if hyperiid species assemblages are congruent with biogeochemical provinces. This study is among the first to examine their large-scale diversity and distribution patterns in the Atlantic Ocean.

Finally, in Chapter 8, I argue in favor of an integrative taxonomic approach to identifying species in the open ocean compared to the use of morphology or DNA barcoding only, and discuss the powers and pitfalls of next-generation sequencing-based methods. In the second part of this chapter, I provide an overview of recent advances in experimental and genetic research elucidating the sensitivity of pteropods to ocean acidification.

ABSTRACT

Pteropods are a widespread group of holoplanktonic gastropod molluscs and are uniquely suitable for study of long-term evolutionary processes in the open ocean because they are the only living metazoan plankton with a good fossil record. Pteropods have been proposed as bioindicators to monitor the impacts of ocean acidification and in consequence have attracted considerable research interest, however, a robust evolutionary framework for the group is still lacking. Here we reconstruct their phylogenetic relationships and examine the evolutionary history of pteropods based on combined analyses of Cytochrome Oxidase I, 28S, and 18S ribosomal rRNA sequences and a molecular clock calibrated using fossils and the estimated timing of the formation of the Isthmus of Panama. Euthecosomes with uncoiled shells were monophyletic with *Creseis* as the earliest diverging lineage, estimated at 41–38 million years ago (mya). The coiled euthecosomes (*Limacina*, *Heliconoides*, *Thielea*) were not monophyletic contrary to the accepted morphology-based taxonomy; however, due to their high rate heterogeneity no firm conclusions can be drawn. We found strong support for monophyly of most euthecosome genera, but *Clio* appeared as a polyphyletic group, and *Diacavolinia* grouped within *Cavolinia*, making the latter genus paraphyletic. The highest evolutionary rates were observed in *Heliconoides inflatus* and *Limacina bulimoides* for both 28S and 18S partitions. Using a fossil-calibrated phylogeny that sets the first occurrence of coiled euthecosomes at 79–66 mya, we estimate that uncoiled euthecosomes evolved 51–42 mya and that most extant uncoiled genera originated 40–15 mya. These findings are congruent with a molecular clock analysis using the Isthmus of Panama formation as an independent calibration. Although not all phylogenetic relationships could be resolved based on three molecular markers, this study provides a useful resource to study pteropod diversity and provides general insight into the processes that generate and maintain their diversity in the open ocean.

INTRODUCTION

Pteropods are a group of holoplanktonic heterobranch gastropod molluscs (Jörger et al., 2010) that are widespread and abundant in the marine zooplankton (e.g., Bednaršek et al., 2012; Burridge et al., in press: Thesis chapter 6). They have been proposed as bioindicators to monitor the effects of ocean acidification because their aragonite shells are exceptionally vulnerable to rising levels of CO₂ in the global ocean (e.g., Fabry et al., 2008; Comeau et al., 2012; Bednaršek et al., 2016; Moya et al., 2016). It is expected that anthropogenic carbon input into the ocean may affect marine life more severely than in the past, because it is happening much faster than, for instance, at the Paleocene-Eocene thermal maximum (PETM) ~56 million years ago (mya; Zachos et al., 2005; Janssen et al., 2012; Zeebe, 2012). During the PETM, massive amounts of carbon were released into the atmosphere and ocean, leading to ocean acidification and warming, and the ocean's calcite saturation depth shoaled by at least 2 km within 2000 years, a situation that persisted for tens of thousands of years (Doney et al., 2009; Zeebe, 2012). This resulted in major shifts in marine planktonic communities, including foraminifers and calcareous phytoplankton, and a major extinction of benthic foraminifers, but probably not of pteropods (Kelly et al., 1996; Bralower, 2002; Zachos et al., 2005, 2008; Gibbs et al., 2006; Schneider et al., 2013; Janssen et al., 2016).

Pteropods comprise the orders Thecosomata and Gymnosomata (De Blainville, 1824). These groups are ecologically distinct: the thecosomes produce mucus webs to feed on microplankton, whilst gymnosomes are active predators that often feed on thecosomes (Gilmer and Harbison, 1986; Van der Spoel and Dadon, 1999). The thecosomes are further divided into the suborders Euthecosomata and Pseudothechosomata (Meisenheimer et al., 1906). The euthecosomes have aragonite shells throughout their lives while the pseudothechosomes have coiled shells or a semi-soft pseudoconch with an aragonite shell only during the larval stage (Van der Spoel and Dadon, 1999; Janssen, 2012). Within the euthecosomes, the superfamily Limacinoidea has coiled shells, and the superfamily Cavolinioidea has uncoiled shells. Gymnosomes have only larval shells, which they shed during metamorphosis into adults (Lalli and Conover, 1976). Most pteropod species are epipelagic, but some species are meso- or bathypelagic (e.g., *Clio andreae*, *C. chaptalii*, *C. piatkowskii*, *C. polita*, *C. recurva*, *Thielea helicoides*, and *Peracle bispinosa*; Bé and Gilmer, 1977; Van der Spoel and Dadon, 1999).

The taxonomy of thecosomes, and especially that of euthecosomes, has been revised frequently and remains disputed, especially at the (super)family level. The most widely used taxonomy (as accepted by the World Register of Marine Species, WoRMS) was proposed by Janssen (2003). In this classification, the Limacnidae (with extant genera *Heliconoides*, *Limacina*, and *Thielea*) are the only family within the superfamily Limacinoidea, whereas most other classifications included the Limacnidae in the Cavolinioidea (Van der Spoel, 1967; Bouchet and Rocroi, 2005). The superfamily Cavolinioidea contains the extant families Cavoliniidae (*Cavolinia*, *Diacavolinia*, *Diacria*), Cliidae (*Clio*), Creseidae (*Creseis*, *Hyalocylis*, *Styliola*), and

Cuvierinidae (*Cuvierina*; Janssen, 2003). In other studies, Cavolinioidea has been ranked as the family Cavoliniidae with three subfamilies: Cavoliniinae (*Cavolinia*, *Diacavolinia*, *Diacria*), Clionae (*Clio*, *Creseis*, *Hyalocylis*, *Styliola*), and Cuvierininae (*Cuvierina*; Van der Spoel, 1967, 1987; Bouchet and Rocroi, 2005). Finally, according to Rampal (1973, 1975, 2011) there are two families within the Cavolinioidea: Creseidae (*Creseis*, *Hyalocylis*, *Styliola*) and Cavoliniidae, comprising the subfamilies Cavoliniinae (*Cavolinia*, *Diacavolinia*, *Diacria*, *Clio*) and Cuvierininae (*Cuvierina*).

Several recent studies have tested pteropod taxonomic hypotheses using genetic data. Pteropods were confirmed as a monophyletic group within the Opisthobranchia based on a sampling of 10 euthecosome and three gymnosome taxa using the three molecular markers Cytochrome Oxidase subunit I (COI) mitochondrial DNA, nuclear 28S, and 18S rRNA (28S and 18S respectively; Klussmann-Kolb and Dinapoli, 2006). Anaspidea was proposed as the most likely sister group of pteropods (Klussmann-Kolb and Dinapoli, 2006), and this was confirmed by phylogenomic analyses of gastropods (Zapata et al., 2014). Within the pteropods, the uncoiled euthecosomes and gymnosomes were recognized as monophyletic groups in molecular phylogenetic analyses (Klussmann-Kolb and Dinapoli, 2006; Corse et al., 2013). Jennings et al. (2010) constructed phylogenies based on COI sequences of 30 pteropod species. They demonstrated that phylogenetic relationships of pteropods above the species level could not be reliably established using COI as the only molecular marker because of the high rate heterogeneity and limited phylogenetic signal of this marker. Corse et al. (2013) proposed an evolutionary scenario for thecosome pteropods based on a cladistic analysis of morphological data of extant species and separate phylogenetic analyses of COI and 28S genes, with pseudo- and euthecosomes splitting first, and coiled euthecosomes as a paraphyletic group from which uncoiled euthecosomes evolved. Based solely on 28S, both Klussmann-Kolb and Dinapoli (2006) and Corse et al. (2013) reported *Creseis* as the earliest diverging member of the uncoiled euthecosomes.

Some euthecosome taxa have been studied in more detail using molecular methods. Based on COI sequences, Hunt et al. (2010) found that Arctic and Antarctic *Limacina helicina* populations represented genetically distinct species. The Creseidae were studied by Gasca and Janssen (2014), who found monophyly of the genera *Creseis*, *Hyalocylis*, and *Styliola* based on COI data. *Cuvierina* and *Diacavolinia* have been studied using integrative taxonomic approaches combining COI and/or 28S data, morphological analyses of shells, and/or geographic information (Maas et al., 2013; Burridge et al., 2015: Thesis chapter 3, in prep.: Thesis chapter 5). Six *Cuvierina* morphotypes with distinct geographic distributions were distinguished based on geometric morphometric analyses of shell shapes (Burridge et al., 2015: Thesis chapter 3), one of which was described as a new species (Burridge et al., 2016: Thesis chapter 4). Burridge et al. (in prep.: Thesis chapter 5) found evidence for a reduction in the number of described *Diacavolinia* species from 24 to a maximal estimate of 13 species based on integrative taxonomic analyses using recently collected specimens as well as museum specimens, including type material.

Pteropods have an extensive fossil record that largely consists of euthecosome shells and larval gymnosome shells (e.g., Janssen, 2007, 2012). Because their fragile shells do not survive significant transport, they are rarely reworked from one sedimentary unit into another, which makes them reliable fossils for biostratigraphic purposes (e.g., Janssen and Peijnenburg, 2014). Combining their fossil record with molecular methods for phylogenetic inference can improve our understanding of the evolutionary history of pteropods, and provides a framework for assessing past and present responses to global change.

Vicariance events in the global ocean, such as the Terminal Tethyan Event (TTE) and uplift of the Isthmus of Panama (IOP), have had profound effects on the evolution of marine organisms (e.g., Lessios, 2008; Cowman and Bellwood, 2013; Bacon et al., 2015; Bowen et al., 2016; O’Dea et al., 2016). These include reduced connectivity by changes in ocean circulation and shifts in centers of marine diversity. However, the onset of these land barriers has been complex and the timing of events is widely debated, with the IOP formation most commonly estimated at ~3 mya (e.g., Harzhauser et al., 2002, 2007; Bacon et al., 2015; O’Dea et al., 2016). Hence, a better understanding of when these events occurred has important implications for using vicariance events for calibrating molecular clocks for different species as well as for cross-validating fossil-calibrated molecular clocks. Jennings et al. (2010) demonstrated that several pteropod species had interspecific levels of sequence divergence between lineages from different ocean basins. Divergent clades for Atlantic and Pacific sister taxa would allow the use of the IOP as a molecular clock calibration.

Here we shed new light on the evolutionary history of pteropods by performing a combined analysis of three molecular markers: COI, 28S and 18S genes. We include 55 pteropod species spanning the diversity of the group and sampled from each ocean basin, including molecular data of seven additional euthecosome, two pseudothecosome, and five gymnosome species relative to prior studies. We use fossil evidence and the dating of the formation of the Isthmus of Panama to reconstruct the evolutionary history of pteropods, thus enabling comparisons between different calibration methods. Our aims are to (1) examine the phylogenetic relationships of pteropods sampled from the global ocean based on COI, 28S, and 18S sequence data and (2) reconstruct the evolutionary history of pteropods using a molecular clock approach.

MATERIALS AND METHODS

SAMPLING AND SPECIMENS

A total of 55 pteropod species were included in this study (treating subspecies as separate species here and subsequently; TABLE S1). Of these, 27 species are uncoiled euthecosomes and eight are coiled euthecosomes, together representing up to 56% of all currently recognized extant euthecosome species, as well as all eight uncoiled and all three coiled genera. In addition, eight pseudothecosome species

are included (35% of all species), representing all five genera. Twelve gymnosome species (23% of all species) are included, representing eight of the 19 genera. Pteropods were collected at a total of 90 stations: 58 in the Atlantic Ocean (40 species), 14 in the Pacific Ocean (14 species), 10 in the Indian Ocean (10 species), six in the Southern Ocean (seven species), and two in the Arctic Ocean (two species; FIGURE 1; TABLE S1). New samples for this study were collected from the Atlantic Ocean and Caribbean Sea during the AMT18, AMT22, ECO-CH-Z, and MAR-ECO expeditions between 2004 and 2012, and from net tows, remotely operated vehicles and bluewater SCUBA dives in the Northwest Atlantic Ocean, Northeast Pacific Ocean, and Gulf of California in 2012 and 2013. Permits were available for sampling in the Gulf of California (permits DAPA / 2 / 080211 / 00217 by Comisión Nacional de Acuacultura y Pesca, CTC / 001340 by La Secretaria de Relaciones Exteriores, and H00 / INAPESCA / DGIPPN / 831 by Secretaria de Agricultura, Ganadería, Desarrollo Rural, Pesca Y Alimentación) and the NE Pacific Ocean (California Department of Fish and Wildlife Scientific Collecting Permit SC-2316). No permits were required for other plankton collections, and the work did not involve any endangered or protected species.

The majority of pteropod specimens were collected from the epi- to upper mesopelagic layer (500–0 m depth) using different types of plankton nets. Sampling details can be obtained from shipboard reports available online (e.g., Atlantic Meridional Transect cruise reports for AMT cruises, Wenneck et al. (2008) for the MAR-ECO cruise, and The University-National Oceanographic Laboratory System (UNOLS), National Oceanic and Atmospheric Administration (NOAA), and Monterey Bay Aquarium Research Institute (MBARI)). Pteropod sequences from remaining locations were available from Klusmann-Kolb and Dinapoli (2006), Hunt et al. (2010), Jennings et al. (2010), Corse et al. (2013), Maas et al. (2013), Gasca and Janssen (2014), Zapata et al. (2014), and BurrIDGE et al. (2015: Thesis chapter 3). Sampling information for all specimens in this study, including collection dates, geographical coordinates, cruise and station numbers, if reported in previous work, are collated in TABLE S1. Images of newly collected specimens are deposited in the Dryad digital repository at DOI: 10.5061/dryad.bp106.

DNA EXTRACTION, AMPLIFICATION, AND SEQUENCING

Genomic DNA was extracted from muscle tissue or entire individuals (when smaller than 3 mm) using the DNeasy blood & tissue Kit (Qiagen). Alternatively, genomic DNA from specimens collected in 2012 and 2013 from the Northwest Atlantic and Northeast Pacific oceans and the Gulf of California was extracted using an AutoGenprep965 high throughput system (AutoGen, Holliston, MA, USA) using manufacturer protocols.

A fragment of ~600 basepairs (bp) of COI was amplified using the primers LCO-1490 (5'-GGTCAACAAATCATAAAGATATTGG-3') and HCO-2198 (5'-TAAACTTCAGGGT GACCAAAAATCA-3'; Folmer et al., 1994). A fragment of ~1000 bp of 28S was amplified using primers C1-F (5'-ACCCGCTGAATTTAAGCAT-3'; Dayrat et al., 2001) and D3-R (5'-GACGATCGATTTGCACGTCA-3'; Vonnemann et al., 2005). The 18S

FIGURE 1. Overview of sampling locations. Black squares indicate sampling locations of new specimens in this study and white squares indicate all known locations of specimens used from other studies. Sampling locations from Klusmann-Kolb and Dinapoli (2006), Hunt et al. (2010), and Corse et al. (2013), are not indicated because no exact localities were given (see TABLE S1).

region of ~1800 bp was amplified by two overlapping fragments for most samples (overlap of ~500 bp). The two fragments were amplified using the primer pairs A1-F (5'-CTGGTTGATCCTGCCAGTCATATGC-3'; Vonnemann et al., 2005) and 18S-KP-R (5'-TTCCCGTGTGAGTCAAATTAAG-3'; this study) and 18S-KP-F (5'-TGGAGGGCAAG TCTGGTG-3'; this study) and 1800R (5'-GATCCTTCCGCAGGTTACCTACG-3'; Vonnemann et al., 2005).

PCR amplification of COI was performed using 25 μ l volumes containing 15.7 μ l ddH₂O, 2.5 μ l 10x PCR buffer, 2.5 μ l dNTPs (1 mM each), 1 μ l MgCl₂, 0.2 μ l BSA (10 mg/ml), 0.2 μ l of each primer, 0.2 μ l SuperTaq, and 2.5 μ l template DNA, or using illustra™ puReTaq Ready-To-Go PCR Beads (GE Healthcare) requiring 20 μ l ddH₂O, 1 μ l of each primer, and 3 μ l template DNA. The PCR cycling steps were an initial denaturation step of 94°C for 180 s followed by 35 cycles of 94°C for 45 s, 45°C for 60 s, and 72°C for 120 s, and a final extension of 72°C for 600 s. Alternatively, for specimens collected in 2012 and 2013 from the Northwest Atlantic and Northeast Pacific oceans, PCR amplification of COI was performed in 10 μ l volumes containing 5.95 μ l ddH₂O, 0.6 μ l MgCl₂, 0.5 μ l dNTPs, 0.25 μ l BSA, 0.3 μ l of each primer, 0.1 μ l Biolase DNA polymerase (BioLine, Taunton, MA, USA), 1 μ l manufacturer-provided buffer, and 1 μ l template DNA, with an initial denaturation at 95°C for 300 s, 40 cycles of 95°C for 30 s, 48°C for 30 s, and 72°C for 45 s, with a final extension at 72°C for 300 s. For most specimens, PCR amplification of both 18S and 28S was performed in 20 μ l volumes containing 8.8 μ l ddH₂O, 4 μ l 5x Phire buffer (Phire), 2 μ l dNTPs (1 mM each), 1.4 μ l 100% DMSO, 0.2 μ l BSA (10 mg/ml), 0.5 μ l of each primer (18S: A1-F and 1800R or A1-F and KP-R and KP-F

and 1800-R, 28S: C1-F and D3-R), 0.2 µl Hot Start *Taq* (Phire) and 2.4 µl template DNA. Alternatively, 25 µl volumes were used, containing 7 µl ddH₂O, 2.5 µl BSA, 1 µl of each primer, 12.5 µl Amplitaq Gold Fast *Taq* (Life Technologies, Grand Island, NY, USA), and 1 µl template DNA. PCR cycling steps were an initial denaturation step of 98°C for 30 s, 35 cycles of 98°C for 5 s, 48°C for 5 s and 72°C for 20 s, a final extension step of 72°C for 60 s, and a cooling step of 4°C for 180 s. Bands were checked on agarose gel followed by a purification step of the PCR product using the QIAquick gel extraction kit (Qiagen, Germany). After a final cycle sequencing reaction using ABI BigDye Terminator cycle sequencing kit v.1.1 (Life Technologies, USA) according to the manufacturer's protocol, PCR products were sequenced by Macrogen Europe, The Netherlands, the Laboratories of Analytical Biology at the Smithsonian National Museum of Natural History, USA, or the Monterey Bay Aquarium Research Institute, USA.

SEQUENCE ALIGNMENTS

We aimed to include as many complete COI, 28S, and 18S fragments for available taxa as possible in our sequence alignments. The data collected in this study was complemented by sequences from prior studies (TABLE S1). For some specimens we combined partitions from different specimens of the same species and the same ocean for the multi-gene alignments (TABLE S1). For inclusion in multi-gene alignments, sequences of at least two of the three markers per taxon had to be available.

We obtained a total of 53 COI, 53 28S, and 46 18S sequences in this study, and used an additional 65 COI, 35 28S, and six 18S sequences from prior studies for various purposes (TABLE S1). We included two outgroup species sequenced by Klussmann-Kolb and Dinapoli (2006) in all alignments: the large sea slug *Aplysia californica* (Anaspidea), and the shelled gastropod *Bulla striata* (Cephalaspidea). These species were chosen as outgroups because *Aplysia californica* is a representative of the most likely sister group of the Pteropoda, and *Bulla striata* represents a possible sister group to Anaspidea + Pteropoda (Klussmann-Kolb and Dinapoli, 2006).

Nucleotide sequences of COI, 28S, and 18S were examined in MEGA 6 (Tamura et al., 2013) and aligned using MAFFT v7. The amino acid alignment of COI (AACOI) was aligned using the MUSCLE algorithm (Edgar, 2004) in MEGA 6. All sites were used for COI as well as for the AACOI alignment. For 28S and 18S, sites with a coverage of <80% in the alignments were removed using trimAl (Capella-Gutiérrez et al., 2009) in Phylemon 2.0 (Sánchez et al., 2011). This resulted in final alignment lengths of 656 bp or 218 amino acids for COI, 941 bp for 28S, and 1683 bp for 18S. To estimate evolutionary relationships among taxa based on single-gene trees, we used an alignment of $N = 117$ sequences representing 53 pteropod species for COI, $N = 87$ sequences (44 species) for 28S, and $N = 52$ sequences (28 species) for 18S. For the multi-gene phylogeny, we used AACOI, 28S, and 18S partitions comprising a subset of 78 specimens to have a more even taxon sampling across groups (42 pteropod species; a maximum of two taxa per species per ocean). The 28S partition was complete and for the other partitions, 77 AACOI sequences were available (only missing for *Limacina bulimoides*), as well as 52 18S sequences (representing all

euthecosome genera except *Thielea*, representing the pseudothecosome genera *Corolla* and *Peracle*, but missing for *Cymbulia*, *Gleba*, and *Desmopteris*, and representing six gymnosome genera except *Notobranchaea* and *Schizobranchium*, regarding only the genera included elsewhere in this study). To produce a time-calibrated phylogeny, we used a subset of 46 sequences (40 pteropod species, a maximum of one sequence per species per ocean) consisting of AACOI ($N = 45$), 28S ($N = 46$), and 18S ($N = 34$) partitions, because the Yule tree prior assumes that all taxa are independent (i.e., reproductively isolated; Gernhard, 2008).

PHYLOGENETIC ANALYSES

We first estimated phylogenetic relationships based on single-gene Maximum Likelihood (ML) analyses, followed by multi-gene ML analyses, and Bayesian, time-calibrated analyses. To estimate evolutionary relationships among taxa based on single as well as combined genes, we applied a ML approach (Felsenstein, 1981) in RaxmlGUI 1.3 (Stamatakis, 2006; Silvestro and Michalak, 2012). We tested for the most appropriate model of sequence evolution per gene separately using the Akaike Information Criterion (AIC) in jModelTest 2.1.3 (Darriba et al., 2012) based on 88 models, and this approach always selected the GTR (General Time Reversible) model with a proportion of invariable sites (I) and gamma distributed rate variation among sites (Γ). For the AACOI alignment, we used the MtZoa model of evolution, because it best represents the evolutionary process and reduces systematic bias (Rota-Stabelli et al., 2009).

For the single-gene ML phylogenies, we applied a ML search followed by a non-parametric bootstrap analysis with 1500, 2000, and 3000 replicates for COI, 28S, and 18S, respectively. For the multi-gene combined ML phylogeny, we used the MtZoa model of evolution for AACOI and GTR + Γ + I for 28S as well as 18S, and applied a ML search followed by 1500 bootstrap replicates. To examine the effect of long-branch taxa on the phylogenetic signal, an additional tree of 75 specimens (40 pteropod species) was generated excluding *Limacina bulimoides* and *Heliconoides inflatus*.

Prior to producing a time-calibrated phylogeny, we independently tested the topology of the dataset in RaxmlGUI using the same methods as described above. We subsequently applied relaxed Bayesian molecular clock analyses with uncorrelated log-normal rates in BEAUti and BEAST 1.81 (Drummond et al., 2012). Because the MtZoa model of evolution was not available in BEAUti 1.81, we instead used the WAG model (Whelan and Goldman, 2001) for AACOI and GTR + Γ + I for 28S and 18S.

The molecular clock analyses used the Yule Process of speciation (Gernhard, 2008) and were calibrated using three different methods as summarized in TABLE 1 (see also Drummond et al., 2012). In all three methods, the stem node of the pteropods was calibrated using a normally distributed secondary calibration derived from a phylogenomic gastropod study by Zapata et al. (2014), and the crown node of the euthecosomes was calibrated using a log-normal distribution based on the geological age of the first known euthecosome pteropod, *Heliconoides* sp., from the Late Cretaceous (Janssen and Goedert, 2016). In the first calibration approach (Method 1), we used the geological ages of the oldest known fossils

TABLE 1. Overview of molecular clock calibration settings using three different methods.

Calibrated node	Calibration type	Calibration method			Calibration age mya
		1	2	3	
<i>Clio pyramidata</i> (excl. <i>C. p. antarctica</i>)	IOP: Atlantic – Pacific			Crown	3.1
<i>Hyalocylis striata</i>	IOP: Atlantic – Pacific			Crown	3.1
<i>Cliopsis krohni</i>	IOP: Atlantic – Pacific			Crown	3.1
<i>Hyalocylis</i>	Fossil: <i>Hyalocylis marginata</i>	Crown	Stem		3.6–2.6
<i>Diacria</i>	Fossil: <i>Diacria sangiorgii</i>	Crown	Stem		11.6–7.2
<i>Cavolinia</i> – <i>Diacavolinia</i>	Fossil: <i>Cavolinia zamboninii</i>	Crown	Stem		16–13.8
<i>Cuvierina</i>	Fossil: <i>Cuvierina torpedo</i>	Crown	Stem		23–20.4
<i>Creseis</i>	Fossil: <i>Creseis corpulenta</i>	Crown	Stem		38–41
<i>Limacina</i>	Fossil: <i>Limacina gormani</i>	Crown			56–47.8
Euthecosomata	Fossil: <i>Heliconoides</i> sp.	Crown	Crown	Crown	79–66
Pteropods vs. outgroup taxa	Secondary: <i>Clione antarctica</i> vs. <i>Aplysia californica</i>	Stem	Stem	Stem	170–90

Method 1 uses fossil ages as crown calibrations, Method 2 uses fossil ages as stem calibrations, and Method 3 uses the formation of the Isthmus of Panama (IOP) as crown calibrations. mya = million years ago; Prior dist. = Prior distribution; SD = Standard deviation.

presumed to belong to the extant euthecosome genera *Hyalocylis*, *Diacria*, *Cavolinia*, *Cuvierina*, *Creseis*, and *Limacina* as log-normally distributed crown calibrations (TABLE 1; Meyer, 1887; Marshall, 1918; Checchia-Rispoli, 1921; Scarsella, 1934; Curry, 1982; Janssen, 2005, 2007; Cahuzac and Janssen, 2010; Janssen and Goedert, 2016). These fossils were of Eocene, Miocene, or Pliocene age (TABLE 1). In the second approach (Method 2), we set these crown calibrations as genus stem calibrations instead, excluding the *Limacina* calibration. The significant genetic differentiation between Atlantic and Pacific populations of the euthecosomes *Clio pyramidata* and *Hyalocylis striata*, and the gymnosome *Cliopsis krohni* was likely a consequence of the emergence of the Isthmus of Panama (IOP). Hence, in a third calibration approach (Method 3) we used the IOP as a normally distributed prior with a mean of 3.1 mya and a standard deviation of 1 million years, accounting for the debated IOP timing (O’Dea et al., 2016). For all approaches, two MCMC chains were run of 10^8 generations each. We sampled trees and log-likelihood values at 10^4 -generation intervals. Sets of trees obtained during independent runs were combined in LogCombiner 1.8.1 (Drummond et al., 2012), and the maximum clade credibility trees were select-

Calibration age Epoch: age	Prior settings					References
	Prior dist.	Offset	Mean	Log (SD)	SD	
Pliocene: Piacenzian	Normal		3.1		1	O’Dea et al., 2016

ed using TreeAnnotator 1.8.1 (Drummond et al., 2012). To cross-validate calibrations and derive independent ages of these nodes, we performed additional runs of 10^8 generations while leaving out one calibration at a time.

RESULTS

SEQUENCE ALIGNMENTS

The numbers of indels in the COI, 28S, and 18S sequence alignments vary considerably between euthecosomes, pseudothecosomes, and gymnosomes. No stop codons or frameshift mutations are present in the COI alignment (656 bp). The same consecutive three codons are missing for all *Limacina*, *Corolla*, *Cymbulia*, and *Gleba* species. Additional deletions of one or two codons are observed for *Hyalocylis* and *Limacina* species. No insertions or deletions are observed in gymnosome sequences. In the trimmed 28S alignment (941 bp), the number of species or genus-specific gaps is highly variable. Within the euthecosomes, *Heliconoides inflatus* sequences have the highest number of gaps (20 bp), followed by 6–15 bp

for *Limacina bulimoides*, *L. trochiformis*, all *Creseis* species, and *Hyalocylis striata*. Within the pseudothecosomes, 15 bp are missing for *Desmopterus* sp., followed by 3–7 bp for *Cymbulia* sp., *Corolla spectabilis*, and *Peracle reticulata*. Of the gymnosomes, only *Spongiobranchaea australis* has a gap (1 bp). In the trimmed 18S alignment (1683 bp), a large number of gaps is found for *Limacina bulimoides* (47 bp), followed by *Creseis clava* (13 bp), and *Heliconoides inflatus* (11 bp). Few gaps are present within the pseudothecosome sequences (1–3 bp for *Corolla spectabilis* and *Peracle reticulata*). Contrary to COI and 28S alignments of gymnosome taxa, some gaps remain in the 18S alignment of the gymnosomes *Pneumoderma atlantica* (10 bp), and 1–2 bp for *Pneumodermopsis* sp., *Spongiobranchaea australis*, *Clione limacina antarctica*, and *Thliptodon* sp.

INDIVIDUAL GENE TREES

Gene trees recovered from separate ML analyses of COI, AACOI, 28S, and 18S datasets generally recover species and genera with moderate to high bootstrap support (>80%), however, higher-level groupings are unstable and unsupported (FIGURES S1–S4). In both COI gene trees (FIGURES S1 and S2 for nucleotides and amino acids, respectively) the coiled *Heliconoides inflatus* and *Thielea helicoides* group with the uncoiled euthecosomes, rendering both superfamilies of Euthecosomata, uncoiled Cavolinoidea and coiled Limacinoidea, polyphyletic. This could be due to long branches of all *Limacina* taxa (coiled), and *Styliola subula* and *Hyalocylis striata* (uncoiled). Higher-level taxa such as the Euthecosomata, Pseudothecosomata, and Gymnosomata are not significantly supported and their relationships are unresolved based on COI. Supported geographic subclades within species sampled from different ocean basins are recovered for Atlantic and Pacific populations of *Cavolinia uncinata*, *Clio pyramidata*, and *Hyalocylis striata* (euthecosomes), and the gymnosome *Cliopsis krohni* (FIGURE S1). In the 28S tree, all genera are recovered with moderate to high bootstrap support, except *Clio* (FIGURE S3). There is one well-supported clade with *Clio pyramidata* and *C. convexa* (96% bootstrap support), with *C. cuspidata* and *C. recurva* falling into the basal polytomy. Relationships between different genera are mostly unresolved, but the genus *Cavolinia* is monophyletic only when *Diacavolinia* is included within *Cavolinia*. *Heliconoides inflatus* is on an exceptionally long branch. Similarly, the 18S tree supports most genera but does not resolve any of the higher-level groupings, likely because of extremely long branches of two species, *Heliconoides inflatus* and *Limacina bulimoides* (FIGURE S4).

MULTI-GENE PHYLOGENIES

Combining COI, 28S, and 18S sequences into a single phylogenetic analysis with the three genes as separate partitions (partially) compensates for the effects of rate heterogeneity within specific partitions between taxa and improves phylogenetic resolution. Concatenated datasets both including (FIGURE S5) and excluding the long-branch taxa *H. inflatus* and *L. bulimoides* (FIGURE 2) have very similar topologies. Both phylogenies recover Pteropoda as a monophyletic group (100 and 99% support, respectively) as well as Euthecosomata (99% in both phylogenies) and

FIGURE 2. Maximum Likelihood phylogeny of pteropods based on the concatenated dataset of Cytochrome Oxidase I (amino acid alignment) and ribosomal genes 28S and 18S (nucleotide alignments) excluding the long-branch taxa *Heliconoides inflatus* and *Limacina bulimoides*. Black squares represent a bootstrap support of $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Supported euthecosome genera are highlighted in coloured boxes, and representative shell shapes of species are drawn on the right, with all scale bars representing 1 mm. Maximum Likelihood phylogeny including the long-branch taxa *Heliconoides inflatus* and *Limacina bulimoides* is shown in FIGURE S5. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

Pseudothecosomata (99% and 98%, respectively). However, in both phylogenies the monophyly of Gymnosomata is not supported due to the exclusion of *Thliptodon* from the clade. The phylogenetic relationships between euthecosomes, pseudothecosomes, and gymnosomes are unresolved based on these three genes.

The uncoiled euthecosomes (eight genera, superfamily Cavolinioidea) are a well-supported monophyletic group (99% support) in the analyses that exclude long-branch taxa, and *Creseis* is the sister group to all other genera within this clade (FIGURE 2). However, relationships between other uncoiled euthecosome genera are unresolved. The coiled euthecosome genera *Thielea* and *Limacina* (superfamily Limacinoidea) are not supported as a clade but represent the earliest diverging branches within Euthecosomata (FIGURE 2), and the phylogenetic position of *Heliconoides* remains unknown. In the phylogeny with long-branch taxa removed (FIGURE 2), the bathypelagic coiled species *Thielea helicoides* is the sister group of all uncoiled euthecosomes with moderate bootstrap support (83%).

Most species and genera are recovered as monophyletic groups in multi-gene phylogenies except *Clio* and *Cavolinia* (FIGURES 2 and S5). *Clio pyramidata*, *C. pyramidata antarctica*, and *C. convexa* represent one well-supported clade and *C. cuspidata* and *C. recurva* represent another unsupported group with unresolved affinities. *Diacavolinia* sp. groups with *Cavolinia* species rendering the genus *Cavolinia* paraphyletic. Within Pseudothecosomata, the pseudoconch genera *Corolla* and *Cymbulia* group separately (100% bootstrap) from the shelled *Peracle* species. The genus *Thliptodon* does not form a supported clade with other gymnosome genera that do represent a well-supported monophyletic group (*Clione*, *Cliopsis*, *Notobranchaea*, *Pneumoderma*, *Pneumodermopsis*, and *Spongiobranchaea*). The latter clade consists of two subclades, one comprising *Clione* and *Notobranchaea* (100% support), and the other containing *Cliopsis*, *Pneumoderma*, *Pneumodermopsis*, and *Spongiobranchaea* (100% support, FIGURES 2 and S5).

TIME-CALIBRATED PHYLOGENIES

For molecular clock analyses, we reduced the number of taxa in the concatenated dataset to one taxon per species per ocean basin, and kept the long-branch taxa *Heliconoides inflatus* and *Limacina bulimoides*. We first performed a ML analysis to confirm that tree topologies were identical with previous multi-gene phylogenies. This is clearly the case, and Gymnosomata also represent a well-supported clade in this analysis (FIGURE S6).

The topologies of Bayesian time-calibrated phylogenies based on three approaches are identical and match unconstrained ML analyses (FIGURES 3, S7 and S8), for calibration methods 1, 2, and 3, respectively). Posterior probabilities of clade support are high for most nodes (>0.95), including the monophyletic euthecosome, pseudothecosome, and gymnosome clades. Within the uncoiled euthecosomes, significant support is observed for several additional clades compared to the ML phylogenies: the *Clio cuspidata/recurva* group, the *Cuvierina* + *Clio cuspidata/recurva* + *Styliola* group, the *Cavolinia/Diacavolinia* + *Hyalocylis* group (only for Methods 1 and 3), and the *Cavolinia/Diacavolinia* + *Hyalocylis* + *Diacria* group.

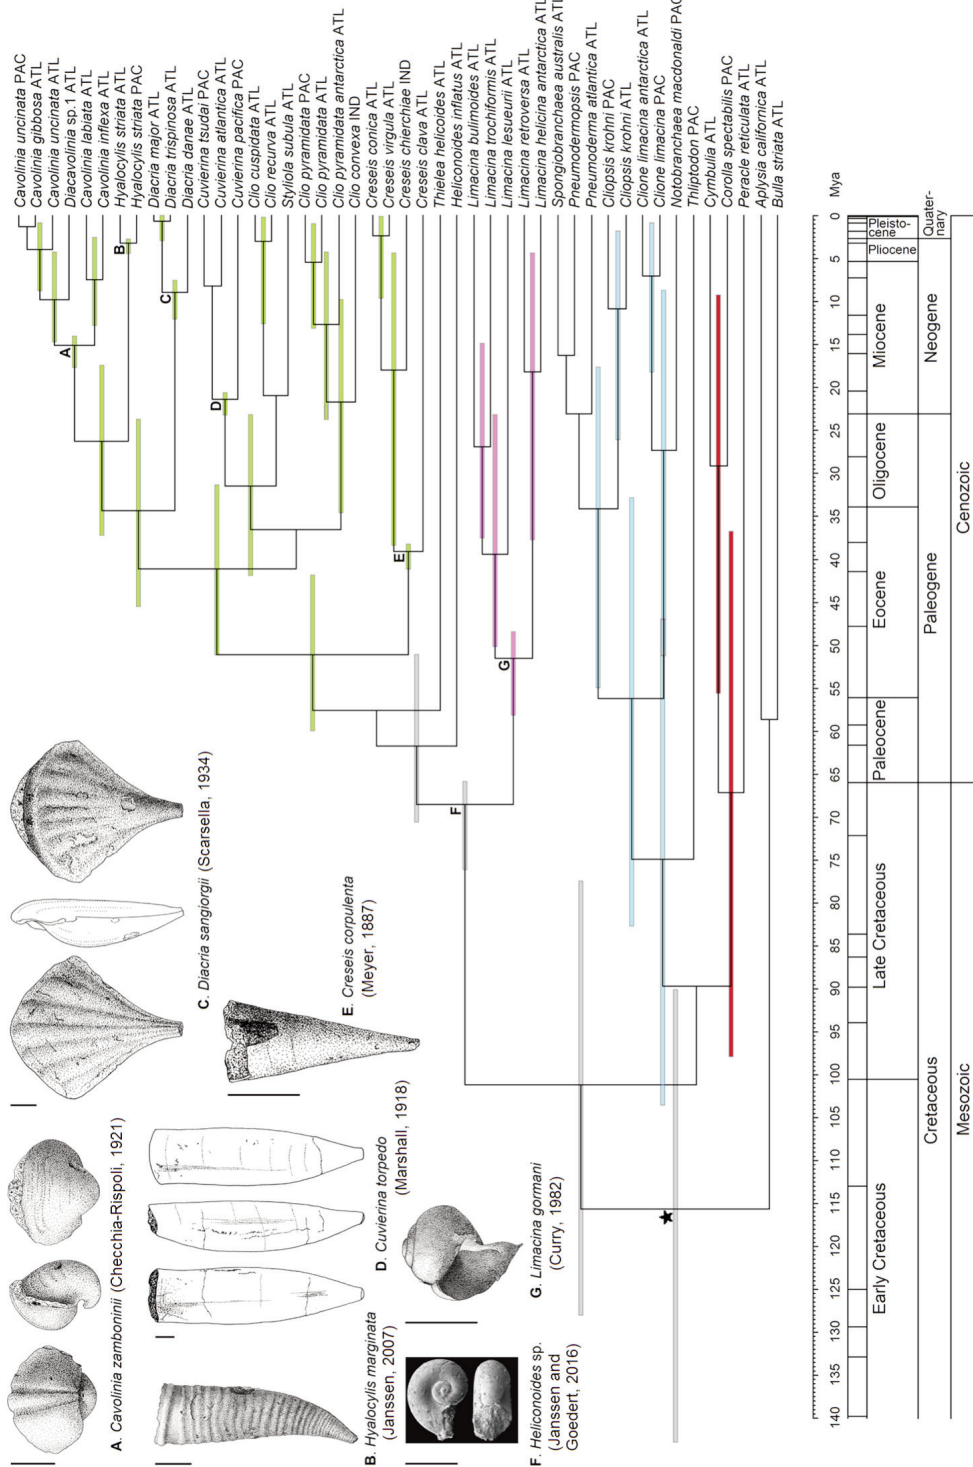

FIGURE 3. Fossil-calibrated phylogeny of pteropods (46 taxa, maximum one sequence per taxon per ocean) following Method 1 with crown calibrations based on the oldest known fossils of *Hyalocylis*, *Diacria*, *Cuvierina*, *Creselis*, *Limacina*, and euthecosomes (see TABLE 1). Drawings of fossils used for calibration are shown on the left, with all scale bars representing 1 mm, and calibrations are indicated with letters A to G. Error bars (95%) are shown only for clades with posterior probabilities ≥ 0.95 in green for uncoiled euthecosomes, purple for coiled euthecosomes, red for pseudothecosomes, and blue for gymnosomes. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

TABLE 2. Overview of node ages as calibrated, as derived from independent runs without specific node calibrations, and as derived from two runs using all calibrations from a specific method.

Group	Calibration type	Calibrated/derived age
Euthecosomata	Fossil: <i>Heliconoides</i> sp.	Calibrated <i>Derived</i>
Cavolinioidea ¹		<i>Derived</i>

The Gymnosomata and of the *Clio cuspidata/recurva* group are supported in time-calibrated, but not in unconstrained multi-gene Maximum Likelihood analyses. The monophyly of uncoiled Euthecosomata (Cavolinioidea) is not supported with a posterior probability of >95 in calibration Method 2 (see TABLE 1). mya = million years ago.

The node ages of pteropod genera derived from molecular clocks are less variable than node ages at higher taxonomic levels. The crown group ages of euthecosomate genera based on fossil ages (Method 1) correspond well with the ages based on IOP calibrations (Method 3), and fossil-based stem calibrations (Method 2) generally lead to much younger crown group ages than other calibration methods (FIGURES 3, S7 and S8; TABLE 2). Cross-validation analyses, in which we left out one of the fossil crown calibrations at a time, show that the derived node ages correspond well with the calibrated ages (Method 1) for *Hyalocylis* (Pliocene), *Diacria*, *Cavolinia/Diacavolinia* (Miocene), and *Limacina* (Eocene). This was not the case for *Cuvierina* (Miocene) and *Creseis* (Eocene), for which crown ages appeared to be

¹ Not supported with posterior probability of >0.95 in molecular clock Method 2

² Supported monophyly in molecular clock, but not in ML analyses

³ Derived from independent run without calibration of this node (100 million generations, 10% burn-in)

⁴ Derived from 2 runs using all calibrations from specific method (2 * 100 million generations, 10% burn-in each)

younger than the fossil evidence, derived at 4.42 and 12.12 mya, respectively. Derived crown group ages based on leaving out one fossil stem calibration per independent run (Method 2) are ~1–3 million years younger than ages derived in Method 1 for *Hyalocylis*, *Diacria*, *Cuvierina*, and *Creseis*, and ~8 million years younger for *Cavolinia/Diacavolinia* (TABLE 2). Derived ages from independent runs that left out one of the three IOP-calibrations each (Method 3) correspond best for *Hyalocylis striata* (derived at 2.99 mya), but are slightly older for *Clio pyramidata* (4.01 mya), and much older for the gymnosome *Cliopsis krohni* (8.62 mya). These ages correspond well with the ages of uncalibrated nodes in Methods 1 and 2 (TABLE 2).

At the higher taxonomic levels (Pteropoda, Euthecosomata, Pseudothecosomata, Gymnosomata) node ages are more variable. The derived age of pteropods versus the outgroup taxa *Aplysia californica* and *Bulla striata* results in a younger age compared to the secondary calibration of this node: 94–74 mya instead of 116–104 mya with large 95% error ranges (TABLE 2). When not used as a fossil crown calibration, the derived age of the euthecosomes appears to be overestimated by all three calibration methods compared to its fossil age (90–75 mya instead of 79–66 mya), but all with large 95% error ranges of 50–59 million years. Derived ages of the pseudothecosomes are 67.25, 56.75, and 58.25 mya, and for the gymnosomes they are 75.0, 63.25, and 65.25 mya, based on calibration methods 1, 2, and 3, respectively (FIGURES 3, S7 and S8).

DISCUSSION

TAXONOMY OF PTEROPODA

Generally, our reconstructed molecular phylogenies match the current morphology-based taxonomy of pteropods. Most species and genera are well resolved and confirmed to be monophyletic and hence provide a useful framework for ecological and evolutionary studies of the group. A taxonomic division of pteropods into euthecosomes, pseudothecosomes, and gymnosomes is also consistent with our data, although their phylogenetic interrelationships remain unresolved. We cannot confirm that euthecosomes are more closely related to pseudothecosomes than they are to gymnosomes, as reflected in current taxonomy, in which the eu- and pseudothecosomes represent the order Thecosomata based on shared morphological characters that set them apart from the order Gymnosomata. The parapodia (wing-like structures) of thecosomes are positioned differently compared to gymnosomes with respect to the head, mouth, and foot-lobes (Pafort-van Iersel and Van der Spoel, 1979; Van der Spoel, 1982). Resolving higher-level taxonomic relationships in pteropods will require additional molecular evidence, such as could be provided by transcriptome data that enable a phylogenomic approach.

All our analyses recover the monophyly of uncoiled euthecosomes supporting the validity of the superfamily Cavolinioidea. We see no reason for changing this name to Orthoconcha, as suggested by Corse et al. (2013). However, the current taxonomy of families within the Cavolinioidea was not supported by our phylogenetic analyses. Currently valid families are Cavoliniidae (*Cavolinia*, *Diacavolinia*, *Diacria*), Cliidae (*Clio*), Creseidae (*Creseis*, *Hyalocylis*, *Styliola*), and Cuvierinidae (*Cuvierina*). This classification corresponds with the overall shape of shells: complex and round for Cavoliniidae, wide and conical for Cliidae, narrow and conical for Creseidae, and bottle-shaped for Cuvierinidae (FIGURE 2). We only found one supported subdivision within Cavolinioidea based on ML phylogenies, with *Creseis* as a monophyletic group and sister clade to the cluster of genera comprising *Cavolinia*, *Clio*, *Cuvierina*, *Diacavolinia*, *Diacria*, *Hyalocylis*, and *Styliola* (FIGURE 2). The time-calibrated phylogenies support additional subdivisions within Cavolinioidea (e.g., *Cavolinia* + *Diacavolinia* + *Hyalocylis*); however, they do not reflect current family-level taxonomy either.

The genus *Clio* was paraphyletic in the multi-gene phylogenies, with the well-resolved clade comprising *Clio convexa*, *C. pyramidata*, and *C. pyramidata antarctica*, being sister to another clade comprising *C. cuspidata* and *C. recurva* that was only supported in time-calibrated Bayesian phylogenies. Morphological characteristics of the two groups support this division: *Clio convexa*, *C. pyramidata*, and *C. pyramidata antarctica* have an elongated protoconch (larval shell) with a subtle transition into the apical spine (larval shell tip), whereas *Clio cuspidata* and *C. recurva* have a round protoconch with a sharp transition into the apical spine (e.g., Janssen, 2012). More genetic information is required to clarify the phylogenetic position of *C. cuspidata* and *C. recurva*, and additional *Clio* taxa should be included in the analysis, such as the deep-dwelling *C. andreae*, *C. chaptalii*, *C. polita*, and *C. piatkowskii*.

Diacavolinia, introduced as a genus by Van der Spoel (1987) was previously included in *Cavolinia* as the single species *Cavolinia longirostris*. We recovered *Diacavolinia* as nested within *Cavolinia*. Specimens identified as *Diacavolinia* sp. 1 were from the Atlantic Ocean and match the Atlantic sequences from Maas et al. (2013) and *Diacavolinia* Group 1 in BurrIDGE et al. (in prep.: Thesis chapter 5). Pacific individuals used in single-gene COI analyses (*Diacavolinia* sp. 2) match the Pacific sequences from Maas et al. (2013) as well as *Diacavolinia* Group 12 in BurrIDGE et al. (in prep.: Thesis chapter 5). The high levels of morphological and genetic diversity found for both *Diacavolinia* and *Cavolinia* suggests that more taxon sampling across all oceans and additional genetic markers are needed to resolve their taxonomy.

The coiled euthecosomes or Limacinoidea consist of a single family, the Limacnidae, which appears to be paraphyletic with respect to the uncoiled euthecosomes. The genera *Heliconoides*, *Limacina*, and *Thielea* are genetically more divergent than the Cavolinioidea genera. This may be a result of their earlier origin compared to uncoiled euthecosomes, and/or higher evolutionary rates, as observed for the conservative markers 28S and 18S. Corse et al. (2013) proposed to rename *Heliconoides inflatus* (listed in their study as *Limacina inflata*) to *Embolus inflata* to emphasize a putative soft polytomy between *Heliconoides inflatus* and other coiled euthecosomes, however, based on the available evidence, we consider the position of *Heliconoides* as unresolved. Moreover, earliest fossil occurrences do not support the presence of a hard polytomy of coiled euthecosome genera (Janssen, 2012; Janssen and Goedert, 2016; Janssen et al., 2016; see next section). Finally, *Embolus* is currently considered a synonym of *Heliconoides* and represents an invalid junior homonym of *Embolus*, a genus of echinoderm (WoRMS).

The single and multi-gene trees strongly supported the taxonomy of the pseudotheosome families Peraclidae (*Peraclis*) and Cymbuliidae (*Cymbulia*, *Corolla*, *Gleba*). However, pseudotheosome species remain poorly studied compared to euthecosomes, and additional taxon sampling of all genera, including *Desmopterus*, is required to resolve their taxonomy.

Only four out of six families and eight of 19 genera of Gymnosomata were included in our analyses, and thus phylogenetic relationships should be regarded

as tentative. Our analyses did not support the current taxonomy of the gymnosome families examined: Clionidae (*Clione*, *Thliptodon*), Cliopsidae (*Cliopsis*), Notobranchaeidae (*Notobranchaea*), and Pneumodermatidae (*Pneumoderma*, *Pneumodermaopsis*, *Schizobranchium*, *Spongiobranchaea*). We found *Clione* as the most likely sister taxon of *Notobranchaea*, and *Thliptodon* grouped separately from all other gymnosome taxa.

EVOLUTIONARY HISTORY

Based on a molecular clock approach using fossils and the IOP as calibrations, we propose a scenario of pteropod evolution, in which this group originated during the Late Cretaceous, and most extant genera evolved during the Late Oligocene and Miocene. The euthecosomes, pseudothecosomes, and gymnosomes most likely evolved during the final stages of the Late Cretaceous (79–66 mya) from which the first *Heliconoides* euthecosome fossil is known (Janssen and Goedert, 2016). Interestingly, this is earlier than previously thought as the time of divergence between the euthecosomes and pseudothecosomes was estimated at 58.6 / 57.3 mya by Corse et al. (2013) based on two different molecular clock methods. However, this may be due to their incorrect assumption that the Early-Eocene (Ypresian) thecosome genus *Altaspiratella* belongs to the Pseudothecosomata.

Among the coiled euthecosomes, the evolution of *Heliconoides* in the Late Cretaceous was followed by the origin of *Limacina* in the Early Eocene at ~56 mya based on fossil records and our time-calibrated molecular phylogeny. The Paleocene-Eocene thermal maximum (PETM) at ~56 mya was probably a critical event in pteropod evolution. Although some studies have suggested that modern pteropod families appeared only after the PETM (e.g., Doney et al., 2009), a recent study of a PETM assemblage of pteropods demonstrated the presence of *Limacina* and *Heliconoides* as well as the extinct genus *Altaspiratella* in this period (Janssen et al., 2016). Based on fossil evidence, it was suggested that most genera that originated after the PETM went extinct before the end of the Eocene at 33.9 mya, when global ocean temperatures dropped (Hodgkinson et al., 1992; Janssen and Peijnenburg, 2017).

We estimated that uncoiled euthecosomes evolved during the Early to Middle Eocene at 51–42 mya, probably from a coiled euthecosome ancestor, as was earlier suggested by Curry (1965) and Curry and Rampal (1979). Putative successive stages of despiralisation have been observed in some pteropod species from the Eocene (Ypresian, 56.0–47.8 mya; Lutetian, 47.8–41.3 mya), as in particular species of the limacinid genus *Altaspiratella*, leading to the creseid genera *Camptoceratops* and *Euchilotheca* (Janssen and Peijnenburg, 2014). *Camptoceratops priscus* was used by Corse (2013) to calibrate the origin of the euthecosomes, but based on its intermediate morphology between coiled and uncoiled taxa its phylogenetic position is considered uncertain. *Creseis* appeared as the first extant uncoiled genus at 41–38 mya (Middle Eocene: Bartonian), followed by a *Clio* representative at 38–34 mya (Late Eocene: Priabonian; Bernasconi and Robba, 1982; Janssen, 1990).

During the Oligocene and Miocene, the (sub)tropical connectivity between the Atlantic and Indian oceans decreased and finally ceased as a result of closure of the

Miocene Tethys Sea (Terminal Tethyan Event TTE; Harzhauser et al., 2002, 2007), and during this period of oceanographic and climatic change many extant pteropod genera appeared. The uncoiled euthecosome genera *Cavolinia*, *Cuvierina*, *Diacria*, *Styliola*, and the *Clio convexa/pyramidata* group originated during the late Oligocene and Miocene between 40 and 15 mya. Corse et al. (2013) estimated that the family Cavoliniidae evolved 47.1 / 30.0 mya, but we did not find evidence for its monophyly. Most pseudothecosome and gymnosome genera probably originated during the Late Oligocene and Miocene (Janssen, 2010). We could not estimate the age of the bathypelagic, coiled euthecosome *Thielea*, but rare fossil evidence suggests at least a Miocene (Tortonian, 11.6–7.2 mya) origin (Janssen, 2012).

The uncoiled euthecosomes *Hyalocylis*, *Diacavolinia* and the *Clio cuspidata / recurva* group appear to be of more recent, Pliocene origin, when the Isthmus of Panama (IOP) became totally emergent, and fossil evidence supports this age (5.3–2.6 mya; Janssen, 2007, 2012). Hence, the age of *Hyalocylis* appears to have been overestimated by Corse et al. (2013) at 38.5 / 16.1 mya. This age rather corresponds with the Late Eocene origin of *Praehyalocylis*, which is the supposed ancestor of *Hyalocylis* (Janssen, 2010). The IOP emergence led to a further reduction in (sub)tropical connectivity between the Atlantic and Indo-Pacific oceans. Isolation of (sub)tropical Atlantic and Pacific populations probably did not occur at the same time for all species. For example, the gymnosome *Cliopsis krohni* may require deeper maximum depths than *Hyalocylis striata* and *Clio pyramidata*, occurring as deep as 1500 m (Troschel, 1854). This could explain the earlier divergence between Atlantic and Pacific populations of *Cliopsis krohni* compared to *Hyalocylis striata* and *Clio pyramidata*. Recent molecular studies of the (sub)tropical *Cuvierina* and *Diacavolinia* taxa also suggested isolation of Atlantic and Indo-Pacific taxa (Maas et al., 2013; BurrIDGE et al., 2015: Thesis chapter 3, in prep.: Thesis chapter 5).

PTEROPODS IN THE ANTHROPOCENE

We present a framework for understanding the evolutionary relationships among pteropods with a focus on shelled euthecosome species based on an integrated analysis of three molecular markers, fossil evidence, and vicariance events. Although not all phylogenetic relationships could be resolved, this study provides new data on the diversity of pteropods, which is an essential first step for their use as bioindicators of the ongoing effects of ocean acidification (e.g., Bednaršek et al., 2016). Recent advances in high-throughput sequencing will allow sampling across the entire genome and will result in better resolved and more robust phylogenies, especially at higher taxonomic levels. Anthropogenic carbon input into the atmosphere and the ocean is occurring over the course of just hundreds instead of thousands of years. Hence, the impacts on surface ocean pH are more precipitous now than during the PETM (Zachos et al., 2005; Zeebe, 2012). Although the PETM may be the most comparable ocean acidification event in the past, its preceding climate conditions were very different from the present day. Continents were configured differently and the global climate was warmer (Zeebe, 2012; Dietmar Müller et al., 2016). Stuecker and Zeebe (2010) found that the current sensitivity

of marine ecosystems to carbon perturbation is likely higher than during the PETM because the ocean's chemistry might have differed substantially. All in all, it is likely that the effects of ocean acidification on pteropods will be unprecedented, and this key group of the zooplankton community will be among the most severely affected.

ACKNOWLEDGEMENTS

We thank J. Huisman for comments on this manuscript, P. Kuperus, B. Voetdijk, L. Dong, and K. Walz for technical assistance in the molecular lab, C. Mennes and V. Merckx for advice regarding phylogenetic and molecular clock analyses, and E. Goetze and A. Tsuda for providing samples. We thank the Southeast Area and Monitoring Program (SEAMAP) for providing samples from their surveys. L. Vásquez (ECOSUR) and J. Lamkin (NOAA) kindly allowed R. Gasca to examine these samples. The authors also thank the captain and crew of the NOAA ship 'Gordon Gunter 1101'. This is contribution number 308 of the Atlantic Meridional Transect Programme. This work was supported by a Netherlands Organisation for Scientific Research (NWO) cruise participation grant, Veni and Vidi grants 863.08.024 and 016.161351 (<http://www.nwo.nl>), respectively, to K.T.C.A. SUPPLEMENTARY INFORMATION

Photographs of pteropod specimens used in this study are available in the Dryad Digital Repository at DOI: 10.5061/dryad.bp106. DNA sequences have been deposited at GenBank under the following accession numbers: MF048913–MF049064.

FIGURE S1. Maximum Likelihood phylogeny of pteropods based on Cytochrome Oxidase I sequences ($N = 117$ sequences of 656 basepairs). Black squares represent a bootstrap support of $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean; ARC denotes the Arctic Sea.

Time-calibrated molecular phylogeny of pteropods

FIGURE S2. Maximum Likelihood phylogeny of pteropods based on Cytochrome Oxidase I protein sequences ($N = 117$ sequences of 218 amino acids). Black squares represent a bootstrap support of $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean; ARC denotes the Arctic Sea.

FIGURE S3. Maximum Likelihood phylogeny of pteropods based on 28S sequences ($N = 87$ sequences of 941 basepairs). Black squares represent a bootstrap support of $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

FIGURE S4. Maximum Likelihood phylogeny of pteropods based on 18S sequences ($N = 52$ sequences of 1683 basepairs). Black squares represent a bootstrap support of $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

FIGURE S5. Combined Maximum Likelihood tree based on Cytochrome Oxidase I protein sequences and 28S and 18S DNA sequences including long-branch taxa ($N = 78$ sequences, max. two sequences per taxon per ocean). Black squares represent bootstrap support $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

FIGURE S6. Combined Maximum Likelihood phylogeny using the same dataset as for the molecular clock analyses ($N = 46$ sequences, max. one sequence per taxon per ocean). Black squares represent bootstrap support $\geq 80\%$, with small, medium and large black squares representing support within genera, of genera, and above genus level, respectively. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

FIGURE S7. Pteropod phylogeny based on a fossil-calibrated molecular clock approach (46 sequences, max. one sequence per taxon per ocean) following Method 2 with stem calibrations based on the oldest known fossils of *Hyalocyllis*, *Diacria*, *Carolinia*, *Cuvierina*, *Cresseis*, and euthecosomes (see TABLE 1). Calibrations are indicated with stars. Error bars (95%) are shown only for clades with posterior probabilities ≥ 0.95 in green for uncoiled euthecosomes, purple for coiled euthecosomes, red for pseudotheosomes, and blue for gymnosomes. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

FIGURE S8. Time-calibrated molecular phylogeny of pteropods (46 sequences, max. one sequence per taxon per ocean) following Method 3 with crown calibrations of *Clio pyramidata*, *Hyalocylis striata*, and *Cliopsis krohni* based on the formation of the Isthmus of Panama (IOP) and the oldest known euthecosome fossil (see TABLE 1). Calibrations are indicated with stars. Error bars (95%) are shown only for clades with posterior probabilities ≥ 0.95 in green for uncoiled euthecosomes, purple for coiled euthecosomes, red for pseudothecosomes, and blue for gymnosomes. Abbreviations ATL, PAC, and IND denote Atlantic, Pacific, and Indian Ocean origins, respectively, including their sectors in the Southern Ocean.

TABLE S1. Overview of sequences used in combined and/or as single-gene phylogenetic analyses based on Cytochrome Oxidase I, 28S rRNA, and 18S rRNA. Numbers in the 9th column indicate their use in (1) single-gene Maximum Likelihood (ML), combined ML and combined Bayesian phylogenies, (2) single-gene ML and combined ML phylogenies, or (3) single-gene ML phylogenies. An asterisk indicates long-branch taxa that were excluded in separate multi-gene ML phylogenetic analyses. Bp = number of basepairs per sequence. *Clione limacina antarctica* sequences were obtained from a transcriptome (T). Picture numbers indicated with an asterisk represent juvenile specimens (available in the Dryad digital repository at DOI: 10.5061/dryad.bp106).

Global biogeography and evolution of *Cuvierina* pteropods

Alice K. Burridge, Erica Goetze, Niels Raes,
Jef Huisman & Katja T.C.A. Peijnenburg

ABSTRACT

Shelled pteropods are planktonic gastropods that are potentially good indicators of the effects of ocean acidification. They also have high potential for the study of zooplankton evolution because they are metazoan plankton with a good fossil record. We investigated phenotypic and genetic variation in pteropods belonging to the genus *Cuvierina* in relation to their biogeographic distribution across the world's oceans. We aimed to assess species boundaries and to reconstruct their evolutionary history. We distinguished six morphotypes based on geometric morphometric analyses of shells from 926 museum and 113 fresh specimens. These morphotypes have distinct geographic distributions across the Atlantic, Pacific and Indian oceans, and belong to three major genetic clades based on COI and 28S DNA sequence data. Using a fossil-calibrated phylogeny, we estimated that these clades separated in the Late Oligocene and Early to Middle Miocene. We found evidence for ecological differentiation among all morphotypes based on ecological niche modelling with sea surface temperature, salinity and phytoplankton biomass as primary determinants. Across all analyses, we found highly congruent patterns of differentiation suggesting species level divergences between morphotypes. However, we also found distinct morphotypes (e.g., in the Atlantic Ocean) that were ecologically, but not genetically differentiated. Given the distinct ecological and phenotypic specializations found among both described and undescribed *Cuvierina* taxa, they may not respond equally to future ocean changes and may not be equally sensitive to ocean acidification. Our findings support the view that ecological differentiation may be an important driving force in the speciation of zooplankton.

Keywords:

Zooplankton, Integrative taxonomy, Geometric morphometrics, Molecular clock, Ecological niche modelling

BACKGROUND

Shelled pteropods (Mollusca, Gastropoda: Thecosomata) are potentially good bioindicators of the effects of ocean acidification, but their application as such is hampered by limited knowledge of their taxonomy, genetic diversity, ecology and distribution patterns. Pteropods are a group of heterobranch gastropods (Jörger et al., 2010) that are a common component of the marine zooplankton. They affect the ocean carbon cycle by producing aragonite shells that can accelerate the export of organic matter from the surface into the deep ocean. Because of their delicate aragonite shells, pteropods have been identified as exceptionally vulnerable to rising CO₂ (e.g., Feely et al., 2004; Orr et al., 2005; Fabry et al., 2008), and hence are widely used to explore the effects of ocean acidification (e.g., Roger et al., 2011; Bednaršek et al., 2012a, 2014; Comeau et al., 2012). Shelled pteropods also may be a particularly informative model system for the study of long-term marine evolutionary processes, because they are metazoan plankton with an abundant fossil record (e.g., Lalli and Gilmer, 1989; Janssen and Peijnenburg, 2014).

Recent studies suggest that marine plankton have higher evolutionary potential than originally thought and may be well poised for evolutionary responses to global change (e.g., Lohbeck et al., 2012; Jin et al., 2013; Peijnenburg and Goetze, 2013). A recent review of population genetic studies of oceanic zooplankton showed that genetic isolation can be achieved at the scale of gyre systems, and appears to be linked to the particular ecological requirements of the organisms (Sa'ez et al., 2003). Molecular phylogenetic studies on calcifying plankton have suggested greater specificity in oceanographic habitat preferences than previously supposed, e.g., in coccolithophores (e.g., De Vargas et al., 2004; Aurahs et al., 2011) and foraminifers (e.g., Darling and Wade, 2008; Aurahs et al., 2011; Sears et al., 2012; Ujiié et al., 2012; Weiner et al., 2012). The evolutionary potential of calcifying plankton is further supported by long-term selection experiments, which have demonstrated rapid functional genetic divergence in response to elevated CO₂ concentrations (Lohbeck et al., 2012; Jin et al., 2013). Hence, calcifying plankton may be capable of rapid evolutionary as well as ecological responses to changing ocean conditions, including future changes driven by global warming and ocean acidification.

The taxonomy of shelled pteropods has generally been based on shell morphology, although some studies have also examined soft parts (e.g., Van der Spoel, 1967; Van der Spoel et al., 1993). Several pteropod taxa have been identified using the traditional approach of univariate measurements of shell dimensions (e.g., Van der Spoel, 1970, 1974; Van der Spoel et al., 1993; Janssen, 2005). Yet, the complex and highly diverse shell morphologies of pteropods also enable detailed geometric morphometric analyses. Several studies have shown that geometric morphometrics can be more powerful in distinguishing taxa than univariate measurements (e.g., Aiello et al., 2007; Mitteroecker and Gunz, 2009; Klingenberg, 2010). Molecular phylogenetic studies suggested that taxonomic revisions will be required (Klussmann-Kolb and Dinapoli, 2006; Jennings et al., 2010; Corse et al., 2013). These studies showed a well-supported separation of species and genera, but relation-

ships among genera are poorly resolved. The first genus-level study of pteropods focused on DNA barcoding of *Diacavolinia*, and emphasized the inadequacy of current systematic understanding of this genus (Maas et al., 2013). The taxonomy of *Creseis*, *Hyalocylis* and *Styliola* was reviewed by Gasca and Janssen (2014).

This study focuses on the genus *Cuvierina*, an excellent model group for an integrative study of zooplankton because it has a worldwide distribution, it is abundantly present in museum collections, and has a well-described fossil record (Janssen, 2005). Moreover, the bottle-shaped adult shells (6–11 mm long) do not change during adult life, and can be easily distinguished from juvenile shells that are shed once the animal is mature (Bé et al., 1972; Lalli and Gilmer, 1989). Extant *Cuvierina* pteropods occur from 45°N to 40°S, in ocean regions with surface water temperatures above ~17°C (Van der Spoel, 1967). Recent taxa are absent from the Mediterranean and Red Seas (Bé and Gilmer, 1977; Janssen, 2005). *Cuvierina* taxa have a diel vertical migration pattern and prefer epipelagic depths, with highest abundance between 100 and 250 m (Bé and Gilmer, 1977). *Cuvierina* taxa are hermaphrodites and internal fertilizers (Lalli and Gilmer, 1989). The most recent taxonomic revision of *Cuvierina* was based on univariate shell measurements and a description of shell micro-ornamentation (Janssen, 2005, 2006a). Based on fossil evidence, Janssen (2005) proposed that extant *Cuvierina* species evolved 5–4 million years ago (mya), with the origin of the first fossil species estimated at 25–24 mya. Janssen (2005) proposed a subdivision of five extant morphospecies divided in two subgenera: *Cuvierina (Urceolarica) cancapae* (Janssen, 2005), *Cuvierina (Urceolarica) urceolaris* (Mörch, 1850), *Cuvierina (Cuvierina) columnella* (Rang, 1827), *Cuvierina (Cuvierina) atlantica* (Bé et al., 1972), and *Cuvierina (Cuvierina) pacifica* (Janssen, 2005). However, recent studies of pteropods have not implemented this species-level revision, resulting in considerable taxonomic confusion (Klussmann-Kolb and Dinapoli, 2006; Jennings et al., 2010; Bednaršek et al., 2012b; Corse et al., 2013). Here, we follow and test the morphological taxonomy of Janssen (2005), referring to the proposed *Cuvierina* taxa as morphotypes.

The overall aim of this study was to obtain a framework of phenotypic, genetic and geographic information to assess species boundaries and the evolutionary history of *Cuvierina* pteropods. To this end, we first applied geometric morphometric analyses of shell outlines using an extensive collection of museum and fresh specimens from the Pacific, Atlantic, and Indian oceans. Secondly, we sequenced a portion of mitochondrial DNA (mtDNA) comprising a fragment of the cytochrome oxidase I (COI) subunit, as well as a portion of the nuclear 28S rDNA gene. Thirdly, we plotted global distribution patterns of *Cuvierina* morphotypes and applied ecological niche modelling to estimate their ecological tolerances. Our specific objectives were (1) to distinguish between and within extant taxa using an integrative approach (as suggested by, e.g., McManus and Katz, 2009), (2) to determine the temporal sequence of evolution in the genus using a fossil-calibrated molecular phylogeny, and (3) to explore the current and past biogeographic context of extant *Cuvierina* taxa.

METHODS

SAMPLES

An overview of all *Cuvierina* samples is listed in TABLE 1 (more detailed information can be found in TABLE S1). Museum samples included specimens from the Natural History Museum of Denmark in Copenhagen (ZMUC) and Naturalis Biodiversity Center (NBC, Leiden, formerly Zoological Museum of Amsterdam (ZMA)). Museum samples were stored in 70% ethanol, but all museum samples had initially been fixed in formalin rendering them unsuitable for genetic analyses. Geographic locations of museum samples were either provided with the samples or obtained from Schmidt (1934), Gibbs (1971), Gibbs et al. (1971), Krueger et al. (1976) or Van Couwelaar (1998). Samples from ZMUC ($N = 712$ from 80 locations, 1-46 specimens per sample) were identified and sorted per morphospecies by A.W. Janssen (2001-2005; Janssen, 2005) and served as reference museum samples for geometric morphometric analyses in this study (FIGURE 1; TABLES 1 and S1). Reference samples were collected during the Danish DANA expeditions between 1911 and 1934 during all seasons (53 locations), and during various other expeditions between 1846 and 1912 (27 locations) such as Leg. Andrea (TABLE S1). Samples from NBC ($N = 214$ from 32 locations, 1-23 specimens per sample) were not identified according to the taxonomic revision of *Cuvierina* by Janssen (2005) and are referred to as unidentified museum samples (FIGURE 1; TABLE 1). These samples were collected during the DANA expeditions between 1911 and 1933 (21 locations), ACRE expeditions (1967-1968, five locations), and Project 101A (1980, six locations; TABLE S1). Fresh samples ($N = 133$ from 53 locations, 1-23 specimens per sample) were collected between 2001 and 2012 during the following expeditions: MP3 (2001, three locations), 0106TRAN

(2001, one location), COOK11MV and 14MV (2001, five locations), DRFT07RR (2001, three locations), VANC10MV (2003, one location), MARECO (2004, three locations), ECO-CH-Z (2007, nine locations, provided by R.A. Gasca Serrano, Unidad Chetumal, Mexico), AMT18 (2008, three locations), R/V Tansei-Maru KT-10-20 (2010, one location, provided by H. Miyamoto, University of Tokyo, Japan), Kilo Moana 1109 (2011, four locations), AMT22 (2012, 14 locations), and KH-11-10 (2011-2012, six locations, provided by A. Tsuda, University of Tokyo, Japan; FIGURE 1; TABLE S1). The collection nets used had mesh sizes between 0.2 and 1 cm. Fresh samples were stored in 96% ethanol. Only mature individuals with intact shells, both museum and fresh specimens, were used for geometric morphometric analyses. All fresh individuals were used for genetic analyses ($N = 133$; TABLES 1 and S1).

GEOMETRIC MORPHOMETRICS

Specimens were photographed in two orientations: ventral and apertural (FIGURE 2). Photographs were taken with a Nikon D100 6 mpx camera (Micro-Nikkor lens 55 mm / 3.5, aperture $f / 16$, shutter speed $1 / 8s$ ISO 200, fixed zoom), which was attached to a stand. For ventral photography, specimens were mounted on photographic film with methyl glucose (60%) to standardize the orientation. For apertural photography, shells were put into small disposable pipette tips. Photographs were adjusted in Adobe Photoshop Lightroom 2-2008 on white balance, sharpness, vibrancy and noise. Files containing pictures selected for analysis were prepared using tpsUtil (Rohlf, 2006). Only well-focused, undamaged adult shells in standardized orientation were used.

Because there are no true landmarks on *Cuvierina* shells, we used semi-landmarks for outlining shells (Gunz and Mitteroecker, 2013). Ventral shell outlines were created tpsDig (Rohlf, 2006) for a total of 1039 specimens, and apertural outlines were applied to a subset of 550 specimens (FIGURE 2; TABLE 1). The ventral outline was created by starting and ending at the distinct transitions from the outside of the shell to the aperture. One separate semi-landmark was placed at the top of the aperture. Using tpsUtil (Rohlf, 2006) the outline was converted to 75 semi-landmarks, separated by equal length, enabling further analyses (FIGURE 2). The apertural outline started with the semi-landmark in the middle of the aperture edge (the upper semi-landmark shown for typical specimens in FIGURE 2), being one of 35 semi-landmarks in which the apertural outline was converted. TpsRelw (Rohlf, 2006) was used to rotate, translate and scale semi-landmark coordinates through generalized least square Procrustes superimposition (GLS; Kendall, 1977, in Zelditch et al., 2004). GLS provided centroid sizes (a size measure depending on surface area) and multiple relative warp axes (RWs; ventral $N = 148$; apertural $N = 70$) per specimen. RWs contain information on shape, with the first RW containing the most shape information. To test for repeatability of RWs, a selection of 44 specimens was photographed in two subsequent series. Intraclass correlation coefficients (ICCs) between the two series were calculated for the first 10 RWs in Past 3.0 (Hammer et al., 2001). RWs were considered repeatable when $ICC > 0.80$. The outline method for geometric morphometric analyses on *Cuvierina* shells was highly repeatable ($ICC > 0.89$ for ventral RWs 1, 2, 4, 5, 6 and centroid size; $ICC > 0.82$ for apertural RWs 1, 2, 4, 5, and centroid size). Only repeatable RWs were used in further analyses of shell shape. To test whether sliding semi-landmarks provided more consistent results, ICCs were also calculated after transformation of semi-landmarks separated by equal-length intervals into sliding semi-landmarks with estimated positions on the outline. This did not improve repeatability; hence only semi-landmarks were used in this study.

The *a priori* classification of reference museum specimens (those identified by Janssen, 2005), was compared to results of clustering by linear discriminant analyses (LDA) in R 3.0.1 (R Development Core Team, 2013). Parameters for identifying morphotypes using LDA were ventral centroid size and ventral RWs 1, 2, 4, 5, 6.

FIGURE 2. Centroid size variation for reference museum specimens of *Cuvierina* in ventral ($N = 712$) and apertural ($N = 352$) orientations. Typical specimens of six morphotypes are shown with outlines transformed to semi-landmarks to allow for geometric morphometric analysis. Lengths of *Cuvierina* shells were between 0.6 and 1.1 cm.

Subsequently, we compared our manual morphotype identifications of previously unidentified museum and fresh specimens to results of LDA-assignment of these specimens to morphotypes. Our manual identification of unidentified specimens was based on ventral centroid size, ventral RWs 1, 2, 4, 5, 6, and if available, apertural centroid size and apertural RWs 1, 3, 4, 5. The performance of the LDA algorithm was tested by cross-validation using a jackknifed confusion matrix in Past 2.17c (Hammer et al., 2011).

To test for significant differentiation between *a priori* defined groups of *Cuvierina* (morphotypes or geographic distributions), we applied non-parametric permutational multivariate analyses of variance (PerMANOVA; Anderson, 2001) in Past 2.17c. We used Euclidean distances applied to ventral and apertural centroid sizes and RWs with ICC > 0.80 (representing 96.75% of shell shape variation). The PerMANOVA *F*-statistic was tested against 9999 non-parametric mutations.

GENETICS

To assess levels of genetic variation within *Cuvierina*, we sequenced 133 individuals for COI mtDNA and 21 individuals for 28S rDNA (TABLE 1). Entire juveniles ($N = 4$) and 2×2 mm of tissue of adults ($N = 129$) were individually placed in BLB buffer (250 mM EDTA, 5% SDS, 50 mM Tris-HCl pH 8.0; Holland, 1993) for at least 24 h. Total DNA was extracted from BLB buffer using the DNeasy blood & tissue kit (Qiagen Benelux B.V., 2006). The extract was resuspended in 100 μ l AE-buffer (Qiagen Benelux B.V.). A 658bp fragment of COI was amplified using the primers LCO1490 (5'-GGTCAACAAATCATAAAGATATTGG-3') and HCO2198 (5'-TAAACTTCAGGGTGACCAAAAAATCA-3'; Folmer et al., 1994). For a subset of 31 individuals, a 965bp 28S rDNA fragment was amplified using the primers 28SC1F (5'-ACCCGCTGAATTTAAGCAT-3') and 28SD3R (5'-GACGATCGATTTGCACGTCA-3'; Dayrat et al., 2001). Most polymerase chain reactions (PCR) of COI and 28S, with total volumes of 25 μ l, contained PCR Beads (GE Healthcare Europe GmbH) with 3 μ l template DNA, 0.5 μ l of each primer, and 21 μ l ddH₂O. Alternatively for COI, PCR solutions (25 μ l) contained 3 μ l template DNA, 2.5 μ l 10x reaction buffer (HT Biotechnology, Cambridge, U.K.), 1 μ l MgCl₂ (25 mM), 2.5 μ l dNTPs (GATC 1 mM each), 0.3 μ l of each primer (10 μ M), 0.15 μ l Taq polymerase (HT Biotechnology), 0.2 μ l BSA (10 mg/ml) and 15.05 μ l ddH₂O. Amplifications were carried out in a PTC-200 DNA Engine Cycler (Bio-Rad Laboratories B.V.) with an initial denaturation of 3 min at 94°C, 35 cycles of 45 s at 94°C, 1 min at 45°C, and 1.5 min at 72°C, followed by final extensions of 10 min at 72°C and 5 min at 4°C. Sequencing of PCR products was carried out using both PCR primers by Macrogen Europe. The genus-level identities of all sequences were confirmed by BLAST searching GenBank (Altschul et al., 1997). Sequences were aligned in CodonCode Aligner 4.1 (CodonCode Corporation, USA, 2013). Additional GenBank sequences were added, namely three for COI (*C. columnella*): FJ876895-7 (Jennings et al., 2010) and one for 28S (*C. columnella*): DQ237984 (Klussmann-Kolb and Dinapoli, 2006).

To estimate evolutionary relationships among COI haplotypes, we applied a Maximum Likelihood (ML) approach (Felsenstein, 1981) in raxmlGUI 1.3, which

only provides GTR-related models of rate heterogeneity for nucleotide data (Stamatakis, 2006; Silvestro and Michalak, 2012). We tested for the most appropriate model of sequence evolution for this dataset using AIC in jModelTest 2.1.3 (Darriba et al., 2012) based on 88 models and the GTR + Γ + I was selected. However, we use 3 codon positions (CP) instead of Γ + I because it is a biologically realistic model for protein coding sequences (following Shapiro et al., 2006). We applied a ML search followed by a non-parametric bootstrap analysis with 2000 replicates. Additionally, we calculated pairwise genetic distances for COI in MEGA 6.0 using the p -distance model of evolution (Tamura et al., 2013).

To test for congruence of mitochondrial clades with nuclear DNA, we reconstructed alleles from 28S genotypes using the PHASE algorithm (Stephens et al., 2001; Stephens and Donnelly, 2003) in DnaSP v5 (Librado and Rozas, 2009) and used these to calculate pairwise genetic distances with the p -distance model of evolution in MEGA 6.0.

We further explored the population genetic structure of *Cuvierina* in the Atlantic Ocean based on the COI fragment using a total of 60 fresh specimens for which morphotypes were assigned (northern *C. atlantica* ($N = 34$), southern *C. atlantica* ($N = 21$) and central Atlantic *C. cancapae* ($N = 5$); TABLE S1). The number of fresh specimens from the Indian and Pacific Oceans was insufficient for population genetic analyses. We obtained haplotype diversity (H) and nucleotide diversity (π ; Tajima, 1983; Nei, 1987) for each population sample and pooled samples per morphotype and/or geographic region using Arlequin 3.5.1.3 (Excoffier et al., 2005). We tested for differentiation between Atlantic morphotypes and between geographic regions within morphotypes (e.g., North Atlantic versus South Atlantic) using ϕ_{ST} based on pairwise differences. These were tested for divergence from the null distribution of no differentiation with 10,000 permutations, as implemented in Arlequin. For all analyses involving multiple simultaneous tests, significance levels were adjusted by application of a sequential Bonferroni correction with an initial alpha of 0.05 (Rice, 1989).

To reconstruct evolution within *Cuvierina* and to provide a phylogenetic perspective of outgroup relationships, 30 *Cuvierina* sequences were compared to other Cavoliniid taxa. This approach was applied to combined partitions of COI (658bp) and 28S (989bp). Outgroup taxa were *Creseis conica*, *Clio pyramidata*, *C. cuspidata*, *C. recurva*, *Diacria danae* and *D. trispinosa*. The AIC in jModeltest 2.1.3 based on 88 models suggested the use of GTR + Γ + I for COI and GRT + Γ for 28S. Firstly, we applied a ML search followed by non-parametric bootstrap analysis with 3500 replicates in raxmlGUI 1.3. For this purpose, we used the GTR + CP substitution model for COI following (Shapiro et al., 2006). Secondly, we applied a relaxed Bayesian molecular clock analysis to combined COI and 28S partitions with uncorrelated lognormal rates in BEAUti and BEAST 1.7.5 (Drummond et al., 2012). For this we used the models suggested by jModelTest 2.13, because CP-based reconstructions failed to reach an Effective sample size (ESS) > 100 for the posterior statistic after two runs of 10^9 generations (burn-in 2×10^8 generations), as visual-

ized in Tracer 1.5 (Rambaut and Drummond, 2009). The tree prior was set to the Yule Process of speciation (Gernhard, 2008) with a random starting tree. Because our dataset consists of intraspecific as well as interspecific sequences, we limited our dataset to one individual per taxon, but used two individuals of *C. pacifica* S to calculate the TMRCA of this clade. We included the most basally positioned individuals for each morphotype based on the ML-phylogeny of COI and 28S combined. Two fossil calibrations were used, one on the root node of the tree (= stem Cavolinoidea) and one for the time of most recent common ancestry (TMRCA) of extant *Cuvierina*. For the first calibration we used the first fossil occurrence of the now extinct Cavoliniid *Camptoceratops priscus* (Wenz, 1923), 47.8-56 mya (Ypresian stage, A.W. Janssen, pers. comm. and in accordance with Corse et al., 2013) and set a lognormal distributed prior [log (Mean) = 8.0; log (Stdev) = 0.7; offset = 48.0]. For the crown node of *Cuvierina* we set a lognormal distributed prior [log (Mean) = 3.0; log (Stdev) = 0.5; offset = 23.0] based on the first occurrence of *Cuvierina torpedo* in the fossil record at 20.4-23 mya (Janssen, 2005, 2006b). The preliminary MCMC chain was 10^7 generations (burn-in 10^6 generations), followed by six runs of 2.5×10^8 generations (burn-in 2.5×10^6 generations each). We sampled trees and log-likelihood values at 10,000-generation intervals. Sets of trees obtained during independent runs were combined in LogCombiner 1.7.5 (Drummond et al., 2012) and the maximum clade credibility tree was selected using TreeAnnotator 1.7.5 (Drummond et al., 2012).

ECOLOGICAL NICHE MODELLING

To test whether *Cuvierina* morphotypes were ecologically differentiated based on their biogeographic distributions, we applied ecological niche modelling (ENM) to estimate their ecological tolerances. Based on geometric morphometric analyses, we plotted global morphotype occurrences on maps containing marine environmental data from the Bio-ORACLE dataset (Tyberghein et al., 2012) in a WGS1984 coordinate system in ArcMap 10.0 (ESRI, USA, 2011) to obtain an indication of geographic distributions in relation to the ecological variables. The number of geo-referenced sampling locations for each morphotype was 69 for *C. atlantica*, 14 for *C. cancapae*, 17 for *C. columnella*, 30 for *C. urceolaris*, 20 for *C. pacifica* N, and 20 for *C. pacifica* S, respectively. We calculated Spearman rank correlation coefficients (ρ) between the environmental variables and performed a principal component analysis (PCA) on all Bio-ORACLE data layers. The PCA was used to select the most informative ecological variables from sets of correlated variables. This reduced the effect of collinearity of environmental variables (Dormann et al., 2013). Six uncorrelated data layers (with ρ ranging from -0.48 to 0.72), all with a special resolution of 5 arcmin (*ca.* 9.2 km), were selected for ENM: maximum monthly sea surface temperature (SST), annual SST range, annual average sea surface salinity (SSS), annual average surface pH, maximum monthly photosynthetically active radiation reaching the ocean surface (PAR) and maximum monthly near-surface chlorophyll *a* concentration. The Bio-ORACLE layers SST, chlorophyll *a* and PAR were based on remotely sensed data (Tyberghein et al., 2012). Maximum monthly

chlorophyll *a* concentration was set to a maximum of 10 mg/m³ and annual average SSS was set to a minimum of 30 PSU as seen in nature. Although *Cuvierina* taxa are most abundant between 100 and 250 m, they migrate daily between surface waters and greater depths (Bé and Gilmer, 1977). It is therefore likely that sea surface variables are an important dimension of *Cuvierina*'s niche. Using MaxEnt 3.3.3 k (Phillips et al., 2006; Elith et al., 2011) we created response curves for these six ecological variables, performed jackknife tests to measure the importance of individual environmental variables in explaining the modelled distribution of each morphotype, and estimated potential niches per morphotype. Response curves were not extrapolated outside the range of observed values. We used the default settings and all presence records ($N = 170$) for training our model. Accuracy of ENMs per morphotype was examined using a null-model methodology using 99 randomisations that allows for significance testing of ENMs (Raes and Ter Steege, 2007). This test corrects for collection bias by restricting the randomly drawn points to all known sampling locations (presence-only data). Niche overlap between pairs of morphotypes was calculated by the Schoener's *D* statistic (Schoener, 1968; Warren et al., 2008) in ENMTools (Warren et al., 2010). A *D*-value of 1 indicates that two species share the same environmental space and a *D*-value of 0 suggests no overlap.

RESULTS

PHENOTYPIC VARIATION

We distinguished six morphotypes in the pteropod genus *Cuvierina* based on geometric morphometric analyses of shell shape and size of reference specimens (FIGURES 2 and 3). Because we found a separation between North and South *C. pacifica* morphotypes (FIGURES 2, 3 and S1, respectively), these were separated in further analyses and are referred to as *C. pacifica* N and *C. pacifica* S. All morphotypes were significantly different from each other in terms of centroid size (ventral $F = 731.7$; $p < 0.001$) except *C. pacifica* N and *C. pacifica* S (FIGURE 2). Separation in size and shape was most evident in ventral orientation. Here, the overall shell shape variation between six morphotypes was significant after strict Bonferroni correction ($N = 712$, 96.89% of shape variation; $F = 1364$; $p < 0.001$). Extremes on the first RW axis (explaining 91.53% of ventral shell shape variation) were represented by the cylindrical *C. atlantica* and the bottle-shaped *C. urceolaris*, respectively (FIGURE 3). Extremes on the second RW axis (explaining 3.61% of ventral shell shape variation) were *C. pacifica* S with a narrow shell bottom (septum) and *C. cancapae* with a broad septum, respectively. In an apertural orientation, two of the six morphotypes (*C. urceolaris* and *C. pacifica* S) were significantly differentiated ($N = 352$; 84.59% of shape variation; $F = 232.1$; $p < 0.001$).

We also found significant variation in shell shape and size *within* morphotypes for *C. columnella* and *C. urceolaris* from different geographic regions. *C. columnella* specimens from the Indian Ocean ($N = 30$) were larger than Pacific specimens ($N = 35$; $F =$

25.44; $p < 0.001$). The opposite was true for *C. urceolaris*: specimens from the Indian Ocean ($N = 137$) were smaller than Pacific specimens ($N = 89$; $F = 123.7$; $p < 0.001$). We found no significant shape and size differences between *C. atlantica* specimens from the northern ($N = 255$) and southern ($N = 28$) Atlantic populations.

Linear Discriminant Analyses (LDA) almost completely matched manual morphotype identifications based on geometric morphometric analyses of unidentified specimens and showed high correspondence with *a priori* classification of reference museum samples. Without assigning samples to ocean basins *a priori*, 96% of all reference specimens ($N = 712$) were assigned to the same morphotype as determined *a priori*. Confidence increased to 99% when samples from the Atlantic and Indo-Pacific were analyzed separately. We compared this assignment method to LDA and found that without separating samples from the Atlantic and Indo-Pacific basins, 91% of all fresh specimens ($N = 113$) and 96% of all unidentified museum specimens ($N = 214$) were assigned to the same morphotypes as in manual identifications. This accuracy increased when samples were distinguished geographically: 96% of all fresh specimens and 99.5% of unidentified museum specimens were assigned to the same morphotype as with our manual method. We chose our manual method as the final identification method because a few specimens could not be identified unambiguously by LDA. These specimens had either shapes or centroid sizes that were on the edges of the total size-range or morphospace of a specific morphotype. Cross-validation demonstrated a high accuracy of the LDA algorithm itself: 98% of Atlantic and 99.5% of Indo-Pacific reference museum samples were identified as true positives.

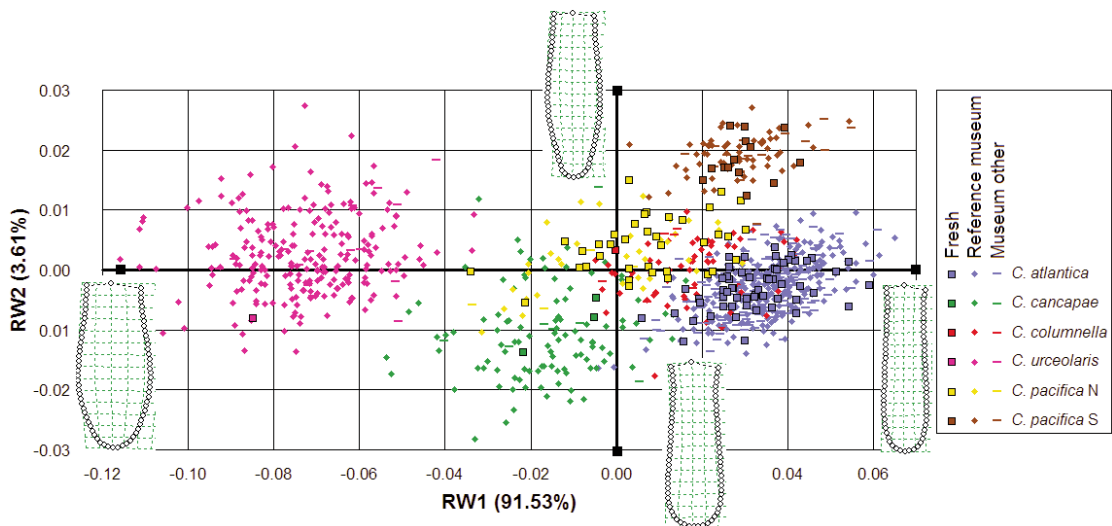

FIGURE 3. Ordination of uncorrected Relative Warp (RW) data of *Cuvierina* in a ventral orientation. Fresh ($N = 113$), reference museum ($N = 712$) and other museum specimens ($N = 214$) are included. Relative Warp 1 explains 91.53% of the total shape variation; RW2 explains 3.61%. Corresponding thin plate splines of the most positive and negative deformations along the axes are indicated to depict the variation in shell shape. Six distinguished morphotypes are indicated in the legend.

GENETIC VARIATION

We found high levels of mitochondrial diversity in a data set of 136 COI sequences collected from global samples of *Cuvierina*, including 127 different haplotypes represented by 166 polymorphic sites (GenBank accession numbers KP292656-KP292788; TABLE S1). We translated COI sequences into amino acids and discarded the possibility of pseudogenes because we found no stop codons and no insertions or deletions. Phylogenetic analysis of COI sequences indicated the presence of three major mitochondrial clades (FIGURES 4 and S2). These three monophyletic clades were highly supported (bootstrap values of 84-99%) and largely congruent with morphotypes as well as geographic distributions (FIGURE 5). The three major clades were named after their geographic distributions; viz., Atlantic, Indo-Pacific and South Pacific (FIGURES 4 and 5). The Atlantic clade contains both the *C. atlantica* and *C. cancapae* morphotypes: we did not find any grouping of these morphotypes, nor did we find any grouping of individuals from either the North or South Atlantic. The Indo-Pacific clade consists of *C. urceolaris*, *C. pacifica* N and *C. columnella* morphotypes. Within this clade, *C. pacifica* N was paraphyletic. Our single specimen of the *C. urceolaris* morphotype grouped with two GenBank sequences from the Indian Ocean (both reported as *C. columnella*, Jennings et al., 2010). The South Pacific clade consists entirely of the *C. pacifica* S morphotype. Average pairwise genetic distances of COI were 4.5-5.1% between major clades and 2.0, 1.7 and 0.8% within clades for the Atlantic, Indo-Pacific and South Pacific, respectively (TABLE S2).

FIGURE 4. Unrooted maximum likelihood tree of 136 Cytochrome Oxidase I gene sequences of *Cuvierina*. Three sequences are from GenBank: FJ876895, Atlantic; FJ876896-7, Indian Ocean. Numbers indicate bootstrap support (only bootstrap values of major clades are shown). Symbols indicate major genetic clades; colors indicate distinct morphotypes (also see FIGURE 5).

Genetic patterns in 28S were not in conflict with our COI data but contained much less variation (0.8% for $N = 31$ representing six morphotypes). We found 11 diploid genotypes represented by 13 phased alleles and a total of eight polymorphic sites (GenBank accession numbers KP292620-KP292649; TABLES S1 and S2). Most *Cuvierina* morphotypes shared 28S sequences, however, *C. pacifica* S and our single *C. urceolaris* specimen had unique single substitutions at positions 866 and 678, respectively (both C instead of T). Average pairwise genetic distances of 28S were 0.03, 0.1 and 0.09% within the Atlantic, Indo-Pacific and South Pacific mitochondrial clades, and 0.14-0.26% between major clades (TABLE S2).

Because we found *C. atlantica* populations in the northern as well as southern Atlantic Ocean, which are separated geographically by *C. cancapae* (FIGURE 5), we tested for spatial genetic structuring. Overall, we found high levels of genetic diversity in Atlantic *Cuvierina* samples (haplotype diversities ranged from 0.99 to 1.0 per sample). Nucleotide diversities were comparable for northern *C. atlantica* ($\pi = 0.020 \pm 0.01$, $N = 34$), southern *C. atlantica* ($\pi = 0.022 \pm 0.01$, $N = 21$) and *C. cancapae* ($\pi = 0.020 \pm 0.01$, $N = 5$). We found significant population genetic structuring of northern versus southern *C. atlantica* populations ($\phi_{ST} = 0.047$, $p = 0.008$), but not between *C. cancapae* and any *C. atlantica* population. This could be due to low sample size of *C. cancapae*.

We reconstructed evolution within the genus *Cuvierina* based on ML and fossil-calibrated Bayesian phylogenetic analyses of the combined COI + 28S sequence

FIGURE 5. Geographic overview of all *Cuvierina* specimens used in this study. Sampling locations are projected on a map of sea surface temperatures (SST) of the warmest ice-free month (MARSPEC data set, Sbrocco and Barber, 2013). See legend for explanation of symbols and colors.

data (FIGURES 6 and S2, respectively). The ML and Bayesian reconstructions established a well-supported monophyly of *Cuvierina* versus outgroup taxa (GenBank accession numbers KP292650-KP292655 and KP292789-KP292794; TABLE S1). Within *Cuvierina*, the South Pacific clade appears basal in both reconstructions, followed by a split between the Atlantic and Indo-Pacific. We found that evolutionary rates of COI and 28S in outgroup taxa were highly variable and outgroup relationships remained largely unresolved (PP < 0.50; ML bootstraps < 40). *Creseis*, the sister taxon of *Cuvierina* based on interpretation of fossil evidence by Janssen (2005), had the fastest evolutionary rate with respect to the other taxa based on our Bayesian analyses (FIGURE 6). Following the TMRCA of 25.3 (28-23, 95% confidence interval) mya (Oligocene) for the genus *Cuvierina*, the first divergence most likely took place between the South Pacific and the Indo-Pacific / Atlantic clades. The Indo-Pacific and Atlantic clades diverged ~16.1 (24.5-7) mya (Miocene). The TMRCA for recent taxa within these three major clades was estimated to be at least 4.7 (13.5-1) mya for the Atlantic, 6.8 (15-2) mya for the Indo-Pacific, and 3.4 (14.5-0.5) mya for the South Pacific clades.

BIOGEOGRAPHY

Cuvierina morphotypes are restricted to warm tropical and subtropical oceanic waters between ca. 43° north and ca. 40° south (FIGURE 5). We found little range overlap between *Cuvierina* morphotypes, especially in the Atlantic and Indian Oceans. However, Pacific distributions of morphotypes of the Indo-Pacific clade (*C. columnella*, *C. pacifica* N and *C. urceolaris*) partly overlapped (FIGURE 5). In the Atlantic Ocean, the *C. cancapae* morphotype is found in equatorial waters, extending as far as 23° south, whereas *C. atlantica* appears in subtropical waters up to 43° north and 35° south. In the Indian Ocean, *C. urceolaris* is found in equatorial waters, whereas *C. columnella* appears in subtropical waters up to 35° south. In the Pacific Ocean, *C. urceolaris* is found in equatorial waters, but *C. columnella* appears in equatorial as well as southern waters up to 40° south. The *C. pacifica* N morphotype has a much wider distribution pattern. It is confined to the Pacific Ocean and has been observed in northern subtropical waters up to 38° north, but also at a few equatorial and southern sampling sites. The *C. pacifica* S morphotype is confined to the large South Pacific gyre (FIGURE 5).

Based on response curves, MaxEnt jackknife scores and Schoener's *D* values, we found evidence for ecological differentiation among all six morphotypes (FIGURE 7; TABLES 2 and S3). The relative contributions of individual oceanographic variables in explaining distribution patterns differed across morphotypes (TABLE 2). In the Atlantic Ocean, maximum monthly SST was most important in explaining the range of *C. cancapae* (41.9% contribution), indicative of its preference for warm waters (FIGURE 7). Other range-explaining variables were annual SST range (22.8%) and annual average SSS (34.6%). The distributional range of *C. atlantica*, however, was predominantly explained by annual average SSS (73.9%), and to a much smaller extent by maximum monthly SST (7.7%). The Indo-Pacific ranges of *C. urceolaris* were to a great extent explained by maximum monthly SST (86.3%), indicating a

preference for warm waters (FIGURE 7), whereas maximum monthly PAR reaching the ocean surface (high) and chlorophyll *a* concentration (low) were important to the distribution of *C. columnella*. No single oceanographic variable was found to predominantly explain the broad range of *C. pacifica* N, but maximum monthly SST and near-surface chlorophyll *a* concentration (both 30.8%) and SSS (21.5%) contributed most. The distribution of *C. pacifica* S was predominantly defined by maximum monthly chlorophyll *a* concentration (57.1%; TABLE 2), indicative of a

FIGURE 6. Fossil-calibrated Bayesian phylogeny of 7 *Cuvierina* and 6 outgroup taxa using COI (658bp) and 28S (989bp). The reconstruction was calibrated by the earliest occurrences in the fossil record of *Camptoceratops priscus* and *Cuvierina torpedo*, indicated by green dots on the nodes. Numbers above major branches indicate posterior probabilities (only values > 0.95 are shown); numbers below major branches indicate ages in million years ago. Branch widths correspond to substitution rates, with thick branches indicating high substitution rates. Symbols for *Cuvierina* indicate major genetic clades; colors indicate morphotypes (also see FIGURE 5). Image of *C. priscus*: Cahuzak and Janssen (2010); and *C. torpedo*: Janssen (2006b). The TTE and IOP are highlighted after estimations by Cowman and Bellwood (2013).

TABLE 2. MaxEnt Jackknife scores representing the relative importance of environmental variables in explaining distribution patterns of *Cuvierina* morphotypes.

% contribution	<i>C. atlantica</i>	<i>C. cancapae</i>	<i>C. columnella</i>	<i>C. urceolaris</i>	<i>C. pacifica</i> N	<i>C. pacifica</i> S
SST max.	7.7	41.9	9.1	86.3	30.8	12.5
Chlorophyll <i>a</i> max.	3.9	0.7	53.4	3.3	30.8	57.1
SSS average	73.9	34.6	1.6	5.9	21.5	7.0
PAR max.	4.1	0.0	31.5	0.0	12.3	7.5
SST range	9.3	22.8	2.6	0.7	4.6	2.0
pH average	1.1	0.0	1.8	3.8	0.0	13.9

SST max. = maximum monthly sea surface temperature (SST), Chlorophyll *a* max. = maximum monthly near-surface chlorophyll *a* concentration (set to a maximum of 10 mg/m³), SSS average = annual average sea surface salinity (SSS, set to a minimum of 30 PSU), PAR max. = maximum monthly photosynthetically active radiation reaching the ocean surface (PAR), SST range = annual SST range, pH average = annual average pH. Highest Jackknife scores represent largest contributions of environmental variables to explaining geographic distributions of morphotypes, but do not provide information on values of selected environmental variables.

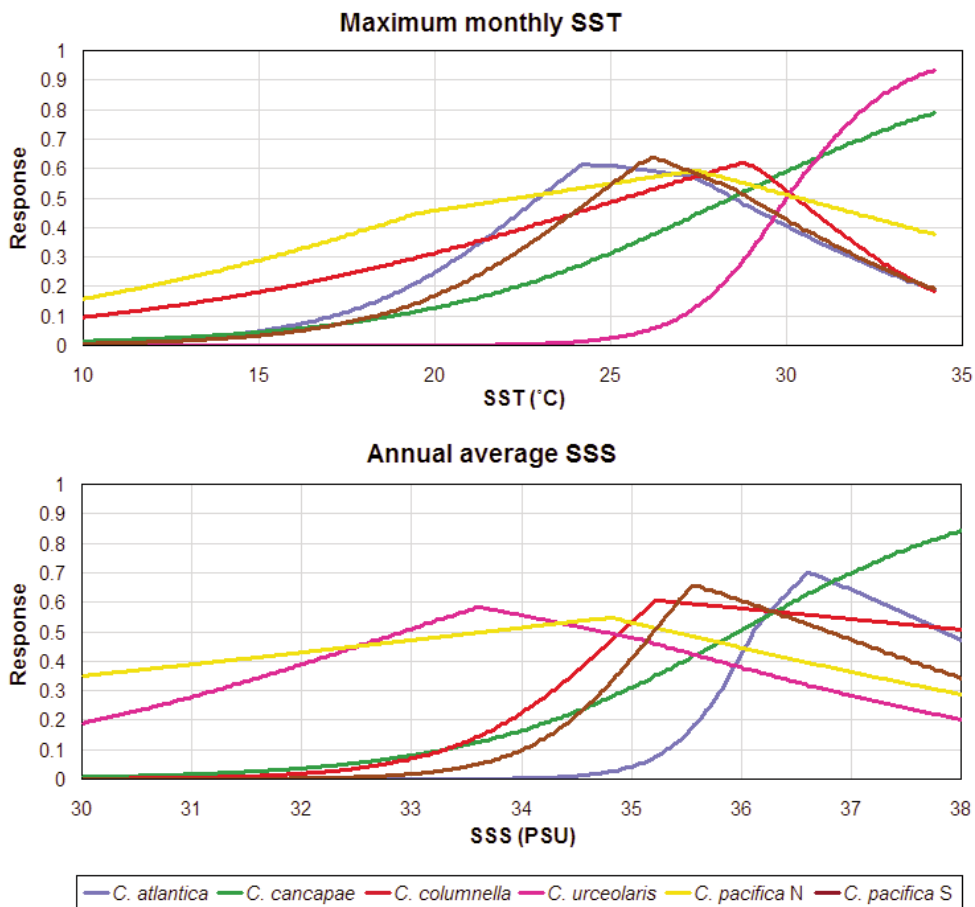

FIGURE 7. Ecological niche modelling response curves for each *Cuvierina* morphotype. Only response curves for maximum monthly Sea Surface Temperature (SST) and annual average Sea Surface Salinity (SSS) are shown.

preference for waters with low surface phytoplankton biomass. All six ENMs per morphotype were accurate according to significance testing using presence-only data (AUC-values 0.884-0.9588; $p = < 0.03$).

DISCUSSION

SPECIES BOUNDARIES

By conducting a global study combining phenotypic, genetic and biogeographic analyses of a zooplankton taxon, we show that the approach of integrative taxonomy can greatly improve our understanding of biodiversity and evolution in the open ocean. We have revealed congruent morphological, genetic and ecological patterns in *Cuvierina*, which all proved to be informative for distinguishing between taxa. We found evidence for six distinct morphotypes based on variation in shell shape and size (FIGURE 3; TABLE 1). This is one more than was formally described by Janssen (2005), although he mentioned the existence of two geographic types of *C. pacifica*. We distinguished three major genetic clades: the Atlantic clade with morphotypes *C. atlantica* and *C. cancapae*, the Indo-Pacific clade with *C. columnella*, *C. urceolaris* and *C. pacifica* N, and the South Pacific clade that consisted entirely of *C. pacifica* S (FIGURE 4). Morphotypes *C. atlantica* and *C. cancapae* are endemic to the Atlantic, *C. pacifica* N and *C. pacifica* S are restricted to the Pacific, and *C. columnella* and *C. urceolaris* occur in both the Indian and Pacific oceans (FIGURE 5). All six morphotypes were clearly disjunct in terms of the combination of shell shape and size, and could be consistently distinguished by LDA. Notably, morphotypes within the same genetic clade were usually the most divergent in morphometric characters. We also found differences in oceanographic habitat preferences, with differences particularly notable within the same genetic clades and ocean basins (see FIGURES 5, 7 and S3). In contrast to the terrestrial domain, the application of ecological niche models for depicting ecological tolerances of pelagic taxa has been rare (e.g., Provan et al., 2009; Robinson et al., 2011). Our ecological niche models have not taken into account diel vertical migration, dispersal limitation and biotic interactions in the prediction of the potential realized niche of the six morphotypes (Robinson et al., 2011). This may explain why morphotypes were not observed throughout their entire modelled potential niches.

Given the widely documented importance of shell morphology in the adaptation of gastropods (e.g., Vermeij, 2002; Rólan-Alvarez et al., 2004), the phenotypic variation found in *Cuvierina* taxa may reflect the interplay between genetic adaptation as well as plasticity in response to environmental conditions. For example, at present there is no genetic evidence for concluding that the *C. atlantica* and *C. cancapae* morphotypes are distinct species. However, genetic differentiation may well be present in other parts of the genome and would be an interesting topic for future research. We hypothesize that interbreeding between *C. atlantica* and *C. cancapae* is unlikely given the clearly disjunct morphologies of adult shells congruent with their respective geographic distributions. The preference of *C. cancapae*

for warmer waters with lower viscosities may explain its more bottle-shaped morphology with a larger surface to body weight-ratio compared to *C. atlantica*. This could be an adaptation to increase drag and thereby reduce sinking rates in warmer waters (Power, 1989). Furthermore, *C. cancapae* has pronounced shell micro-ornamentation which may also increase drag, whereas *C. atlantica* shells are completely smooth. All extinct *Cuvierina* and *Ireneia* taxa had pronounced shell micro-ornamentation and occurred in warm waters (Janssen, 2005), suggesting that micro-ornamentation is the ancestral character state. Common garden studies of other gastropod molluscs have shown that axes of shell shape variation often have a large genetic component, such as *Nucella lapillus* (h^2 of 0.51: Colson et al., 2006) and *Littorina saxatilis* (h^2 of 0.35-0.7: Conde-Padin et al., 2007).

We tentatively consider interbreeding between morphotypes within the Indo-Pacific clade unlikely as well, pending additional sampling and molecular data. We find clearly disjunct morphologies, extreme size differences and strong ecological preferences of *C. urceolaris* (warm tropical waters), *C. columnella* and *C. pacifica* N (both in subtropical, oligotrophic gyres) morphotypes. The shell of *C. urceolaris* is bottle-shaped with pronounced micro-ornamentation similar to *C. cancapae*. This may be explained by the same hypothesis as for *C. cancapae* in the Atlantic Ocean, because *C. urceolaris* also occurs in the warmest waters with lowest viscosities in the Indo-Pacific. Similar to our findings, other studies have reported much stronger phenotypic divergence than (neutral) genetic divergence in marine populations (e.g., Mariani et al., 2012), in particular in taxa with high dispersal potential (e.g., Luttikhuisen et al., 2003; Hollander, 2008; André et al., 2011; Yebra et al., 2011).

Ecological barriers to dispersal and similar distribution patterns as for *Cuvierina* are found in several other open ocean plankton taxa, such as *Diacavolinia* pteropods, foraminifers, krill and copepods. *Diacavolinia flexipes*, *D. angulosa* and *D. grayi* show a zonation of equatorial and subtropical distribution patterns in the Indian Ocean similar to *C. urceolaris* and *C. columnella* distributions (Van der Spoel et al., 1993). Like *C. pacifica* S, the krill species *Euphausia gibba* is endemic to the large South-Pacific gyre (Van der Spoel and Heyman, 1983). The presence of a disjunct distribution pattern as for *C. atlantica* in the Atlantic Ocean is also observed for the pelagic copepod genus *Pleuromamma* (Goetze, 2011; Halbert et al., 2013) and the mesopelagic copepod *Haloptilus longicornis* (Norton and Goetze, 2013). However, unlike *H. longicornis*, the *C. atlantica* morphotype is unable to reach the Indian Ocean around South Africa, where a warm current from the Indian Ocean impinges a cold current from the Southern Ocean. Numerous clades of planktonic foraminifers also have distribution patterns that are predominantly based on latitudinal zonation of water masses (e.g., Darling and Wade, 2008).

Based on results from this study, we do not find support for a subdivision into the subgenera *Cuvierina* (containing *C. atlantica*, *C. columnella*, *C. pacifica* N and *C. pacifica* S) and the more bottle-shaped *Urceolarica* (*C. urceolaris* and *C. cancapae*) as proposed by Janssen (2005, 2006a). We find evidence that *C. pacifica* N and *C. pacifica* S are distinct species because they belong to different genetic clades (COI

and 28S) and are morphologically disjunct. Because the holotype of *C. pacifica* belongs to the *C. pacifica* S morphotype, we propose a limitation of the description of *C. pacifica* to *C. pacifica* S and a new taxonomic description for the *C. pacifica* N morphotype (BurrIDGE et al., 2016: Thesis chapter 4). However, because we found no molecular evidence to support the species status of morphotypes within the Atlantic and Indo-Pacific clades, we consider it possible that they represent ecophenotypic varieties or incipient species.

EVOLUTION IN *CUVIERINA*

Based on a fossil-calibrated molecular phylogeny, we propose a biogeographic scenario for the evolution of *Cuvierina* morphotypes that is influenced by decreasing connectivity between the three world oceans since the Miocene (FIGURE 6). The now extinct ancestral genera *Spoelia*, *Johnjagtia* and *Ireneia* originated during the Oligocene at 34-33 mya as an offshoot of the Creseidae according to Janssen (2005). The first *Cuvierina* was thought to have originated directly from *Ireneia* (Janssen, 2005). However, the outgroup relationships of *Cuvierina* remain poorly resolved possibly because ancestral genera, as well as many Miocene and Pliocene *Cuvierina* taxa, are now extinct (e.g., *C. torpedo*, *C. paronai*, *C. grandis*, *C. curryi*, *C. intermedia*, *C. jagti*, *C. inflata*, *C. ludbrookii*, *C. astesana*, and *C. miyakiensis*; Janssen, 2005, 2006a,c, 2007, 2012). There was high connectivity between the three world oceans at the time of divergence between the South Pacific genetic clade and the Atlantic and Indo-Pacific *Cuvierina* clades at 25.3 (28-23) mya (Late Oligocene), but it is unknown for how long the South Pacific clade has been endemic to the large South Pacific gyre. The divergence between the Atlantic and Indo-Pacific clades of 16.1 (24.5-7) mya (Miocene) coincides with the Tethys Sea closure, suggesting a vicariant model of divergence, with the Indo-Pacific clade diverging from the Atlantic clade in the Indian Ocean and later dispersing to the Pacific basin. Until the Terminal Tethyan Event (TTE, 12-18 mya, Cowman and Bellwood, 2013), the Atlantic and Indian oceans were connected through the Tethyan Seaway, but pelagic connectivity was probably reduced from \pm 21 mya onwards (Harzhauser et al., 2002, 2007). Dispersal between the Atlantic and Pacific oceans was possible until \pm 3.1 mya with the final closure of the Isthmus of Panama (IOP, Cowman and Bellwood, 2013). However, there are no clear indications of vicariance events of Atlantic and Pacific *Cuvierina* associated with the IOP (FIGURE 6). The estimated TMRCA of the three extant clades correspond very nicely with the estimates based on fossil evidence (5-4 mya: Janssen, 2005).

Connectivity between the three major oceans is now much more restricted at tropical and subtropical latitudes than in the Early Miocene. The Indo-West-Pacific region (IWP) does not seem to represent a physical barrier today, but could have functioned as such between Indian and Pacific populations of *C. columnella* and *C. urceolaris* during glacial periods when sea levels dropped (e.g., Gaither et al., 2010). This is a possible explanation for the subtle morphometric differences between Indian and Pacific *C. urceolaris* and *C. columnella* specimens. The IWP has also been considered an intermittent barrier to dispersal for several copepods

(Goetze, 2005, 2011). In these studies, significant population genetic structuring was found between Indian and Pacific populations of *Eucalanus hyalinus* and *E. spinifer* (Goetze, 2005) and *Pleuromamma xiphias* (Goetze, 2011).

Physical and ecosystem properties of different Atlantic water masses may be key to incipient speciation within the Atlantic clade. Our population genetic analyses of *C. atlantica* suggest that there is a significant degree of structuring between populations in the northern and southern subtropical gyre systems in the Atlantic Ocean. If genetic structure is interpreted in light of gene flow, this implies a more limited dispersal than expected for open ocean holoplankton. Combined with the disjunct distribution of *C. atlantica* populations, this suggests that the equatorial upwelling waters in the Atlantic represent a significant barrier to dispersal. This equatorial dispersal barrier was also found for the mesopelagic copepod *Haloptilus longicornis*, for which a genetic break was observed between populations in the northern and southern oligotrophic Atlantic gyres (Norton and Goetze, 2013). By contrast, the equatorial Atlantic offers an ecological niche for *C. cancapae*.

CONCLUSION

Given the distinct ecological and phenotypic specializations found among both described and undescribed *Cuvierina* taxa, they may not respond equally to future ocean changes and may not be equally sensitive to ocean acidification. Because the presence and strength of open ocean dispersal barriers depends on the ecological niche of a species, the capacity of a species to adapt to or to track a suitable habitat may vary across closely-related taxa (Peijnenburg and Goetze, 2013). Although open ocean evolution is partially driven by vicariance, our findings support the view that ecological differentiation may also be a major driving force of speciation for zooplankton.

ACKNOWLEDGEMENTS

We are grateful to A.W. Janssen for his ideas, inspiration for this research, and many articles on pteropod fossils. We are indebted to H. Miyamoto, A. Tsuda and R.A. Gasca Serrano who generously provided freshly collected *Cuvierina* samples from diverse regions in the world. We thank J. van Arkel for his assistance concerning specimen photography, to P. Meirmans for his introduction to statistical analyses in R, to V. Merckx for his advice on phylogenetic methods and to L. Dong, B. Voetdijk, and P. Kuperus for technical assistance in the IBED molecular lab. Finally, we thank P. Tarroso, A.W. Janssen, S.B.J. Menken, B.W. Hoeksema and the anonymous reviewers for their helpful comments on this manuscript, and W. Renema, E. Michel, J. Todd, Y. Young and O.S. Tendal for insightful discussions and inspiration. This study was partially supported by the UK Natural Environment Research Council National Capability funding to Plymouth Marine Laboratory and the National Oceanography Centre, Southampton. This is contribution number 264 of the AMT programme. A.K. Burrige was supported by The Malacological Society of London Research grant, N. Raes by the Netherlands Research Council NOW-ALW grant 819.01.014, E. Goetze by NSF grants OCE-1029478 and OCE-1338959, and K.T.C.A. Peijnenburg by SYNTHESYS grant DK-TAF-5199 and NWO-VENI grant 863.08.024. The authors declare that they have no competing interests.

SUPPLEMENTARY INFORMATION

The data set supporting the results of this article is available at the Dryad Digital Repository at DOI: 10.5061/dryad.7n1q4, and DNA sequences have been deposited at GenBank under the following accession numbers: KP292620-KP292794.

SUPPLEMENTARY INFORMATION 1. Centroid size and uncorrected RW (Relative warp) data of all *Cuvierina* shells in ventral as well as apertural orientations. Relative contributions of RW axes to shell shape variation are included. The first sheet contains ventral data of 113 fresh, 712 reference museum, and 214 other museum specimens. The second sheet contains apertural data of 115 fresh, 352 reference museum, and 83 other museum specimens.

SUPPLEMENTARY INFORMATION 2. Photographs of 1039 *Cuvierina* shells in a ventral orientation used for geometric morphometric analyses in this study.

SUPPLEMENTARY INFORMATION 3. Photographs of 550 *Cuvierina* shells in an apertural orientation used for geometric morphometric analyses in this study.

FIGURE S1. Ordination of uncorrected RW data of *Cuvierina* in an apertural orientation. Fresh ($N = 115$), reference museum ($N = 352$) and other museum specimens ($N = 83$) are included. Relative Warp 1 explains 56.01% of the total shape variation; RW2 explains 22.86%. Corresponding thin plate splines of the most positive and negative deformations along the axes are indicated to depict the variation in shell shape. Six distinguished morphotypes are indicated in the legend.

FIGURE S2. Maximum likelihood tree of 30 *Cuvierina* specimens and six outgroup taxa using COI (658bp) and 28S (989bp). Numbers indicate bootstrap support (only bootstrap values of major clades are shown). Symbols for *Cuvierina* indicate major genetic clades; colors indicate distinct morphotypes (also see FIGURE 5).

FIGURE S3. Geographic overview of all *Cuvierina* specimens used in this study. Sampling locations are projected on a map of annual average sea surface salinities (SSS; MARSPEC data set, Sbrocco and Barber, 2013). See legend for explanation of symbols and colors.

**Revision of the genus *Cuvierina* Boas, 1886
based on integrative taxonomic data,
including the description of a new species
from the Pacific Ocean
(Gastropoda, Thecosomata)**

Alice K. BurrIDGE, Arie W. Janssen & Katja T.C.A. Peijnenburg

ABSTRACT

Shelled pteropods (Gastropoda, Thecosomata, Euthecosomata) are a group of holoplanktonic gastropods that occur predominantly in the surface layers of the world's oceans. Accurate species identifications are essential for tracking changes in species assemblages of planktonic gastropods, because different species are expected to have different sensitivities to ocean changes. The genus *Cuvierina* has a worldwide warm water distribution pattern between ~36°N and ~39°S. Based on an integrative taxonomic approach combining morphometric, genetic, and biogeographic information, the two subgenera of *Cuvierina*, *Cuvierina s. str.* and *Urceolarica*, are rejected. A new species is introduced: *Cuvierina tsudai* **sp. n.**, which has to date been considered the same species as *Cuvierina pacifica*. *Cuvierina tsudai* **sp. n.** is endemic to the Pacific Ocean and is characterised by a shell height of 7.2-8.0 mm, a moderately cylindrical shell shape, the absence of micro-ornamentation and a triangular aperture. *Cuvierina pacifica* is restricted to the centre of the oligotrophic southern Pacific gyre, has a shell height of 6.6-8.5 mm, a more cylindrical shell shape, no micro-ornamentation and a less triangular aperture than *C. tsudai* **sp. n.**

INTRODUCTION

Pteropods are holoplanktonic heterobranch gastropods classified in a superorder comprised of the orders Thecosomata and Gymnosomata, commonly referred to as 'sea butterflies' and 'sea angels', respectively (Lalli and Gilmer, 1989; Pierrot-Bults and Peijnenburg, 2015). The order Thecosomata consists of Euthecosomata that have sinistrally coiled or straight, bilaterally symmetrical shells, and Pseudothecosomata that have either sinistrally coiled shells, an internal gelatinous pseudoconch, or are shell-less in the adult stage (Meisenheimer, 1905; Tesch, 1913). Pteropods play an important role in marine food webs (Jörger et al., 2010), and although most species occur in warm tropical and subtropical waters, the highest abundances have been observed for some (sub)polar cold water species (Bé and Gilmer, 1977; Van der Spoel and Heyman, 1983; Bednaršek et al., 2012; BurrIDGE et al., in press: Thesis chapter 6). Because of their thin-walled, aragonite shells, euthecosomes are exceptionally vulnerable to the effects of ocean acidification (e.g., Fabry et al., 2008; Bednaršek and Ohman, 2015; Gattuso et al., 2015; Moya et al., 2016).

The genus *Cuvierina* is a remarkable group of shelled pteropods with relatively large (5.1-11.1 mm), straight, bottle-shaped shells (Janssen, 2005). Ever since *Cuvierina* was described as a mollusc genus (as *Cuvieria* Rang, 1827, emended by Boas, 1886), it has often been considered to consist of a single species, *C. columnella* (Rang, 1827), the type species of the genus by monotypy. The first taxonomic division within the genus came with the description of a second *Cuvierina* species, introduced as *Cuvieria urceolaris* (Mörch, 1850), but in later literature it was often interpreted as a form or subspecies of *C. columnella* (e.g., Tesch, 1913; Van der Spoel, 1967; Rampal, 1975). A third form, *Cuvierina columnella* f. *atlantica*, was described by Van der Spoel (1970), and validated as a taxon of the species group by Bé et al. (1972). Bé and Gilmer (1977) interpreted the morphological differences between the three taxa as infraspecific variability. Contrarily, Rampal (2002) distinguished these taxa as independent species but introduced the taxon *C. spoeli* to replace the taxonomically invalid *Cuvierina columnella* f. *atlantica*. Because the holotype of *C. spoeli* was from the Indian Ocean, where *C. atlantica* is absent, it rather represented *C. columnella* and was rejected as a valid species by Janssen (2005). Two further extant species, *C. cancapae* and *C. pacifica*, were described by Janssen (2005).

According to the most recent taxonomic revision of *Cuvierina*, five extant species were assigned to two subgenera based on shell morphology and supposed lineages of fossil occurrences since the early Miocene (Janssen, 2005, 2006). The subgenus *Cuvierina* s. str. consisted of *C. atlantica*, *C. columnella*, and *C. pacifica*, which are characterised by relatively slender, cylindrical shells, triangular rather than kidney-shaped apertures and the presence (*C. columnella*) or absence (*C. atlantica*, *C. pacifica*) of micro-ornamentation. Two geographical varieties were recognised within *C. pacifica*, one from the North Pacific and the other from the South Pacific, but were not formally introduced as new species. The subgenus

Urceolarica, containing *C. cancapae* and *C. urceolaris*, is characterised by more inflated, bottle-shaped rather than cylindrical shells, pronounced micro-ornamentation, and kidney-shaped rather than triangular apertures.

All extant *Cuvierina* species are restricted to the surface layers of tropical and subtropical waters from ~45°N to ~40°S. In the Atlantic Ocean, *C. atlantica* occurs in the subtropical gyres and *C. cancapae* is found in tropical waters. In the Indian Ocean, *C. columnella* is found in the southern subtropical zone and *C. urceolaris* occurs in tropical waters and further south along Madagascar towards South Africa. *Cuvierina columnella* and *C. urceolaris* also occur in the Pacific Ocean along with *C. pacifica* (Janssen, 2005; BurrIDGE et al., 2015: Thesis chapter 3).

BurrIDGE et al. (2015: Thesis chapter 3) examined the diversity, distribution, and evolution of *Cuvierina* taxa using integrative geometric morphometric, molecular, and biogeographic methods. They confirmed that the five species described for *Cuvierina* species have significantly different shell shapes and that *C. pacifica* consists of two disjunct morphometric groups, registered as *C. pacifica* N and *C. pacifica* S in their study. Three genetic lineages were distinguished based on mitochondrial Cytochrome Oxidase I DNA: the Atlantic lineage with *C. atlantica* and *C. cancapae*, the Indo-Pacific lineage with *C. columnella*, *C. urceolaris*, and *C. pacifica* N, and the South Pacific lineage with *C. pacifica* S. A new taxonomic description of *C. pacifica* N is required because the holotype of *C. pacifica* has the shell shape of *C. pacifica* S.

Based on the findings of Janssen (2005) and the integrative approach of BurrIDGE et al. (2015: Thesis chapter 3) the taxonomy of the genus *Cuvierina* is revised. The subgenera *Cuvierina s. str.* and *Urceolarica* are rejected, a new species, *C. tsudai*, is described from the Pacific Ocean, and the species description of *C. pacifica* is restricted to the South Pacific lineage. A taxonomic key is provided for the identification of *Cuvierina* species.

METHODS

Two approaches were used to distinguish between *C. tsudai* and *C. pacifica* based on differences in shell shape. First, simple measurements of shell height and width, aperture diameters, and position of maximum shell width as applied to museum specimens by Janssen (2005) were used to distinguish between *C. tsudai* and *C. pacifica*. Second, geometric morphometric data of shell shapes in ventral and apertural orientations were used for 168 adult specimens of *Cuvierina* that were registered as *C. pacifica* N or *C. pacifica* S in BurrIDGE et al. (2015: Thesis chapter 3). The specimens corresponded to museum specimens as identified and measured by Janssen (2005, $N = 92$), additional museum specimens ($N = 24$), and recently collected fresh specimens ($N = 52$). Geometric morphometric methods consisted of digitising shell outlines using tpsDig and tpsUtil (Rohlf, 2006) to contain 76 ventral and 37 apertural semi-landmarks per shell, after which a generalised least square Procrustes superimposition was applied (GLS, Kendall, 1977 in Zelditch et al., 2004) to rotate, translate, and scale the semi-landmark coordinates. A subsequent thin-plate spline (TPS) analysis (e.g., Zelditch et al., 2004) provided centroid sizes, a size

measure depending on surface area, and multiple relative warp axes per specimen, containing information on shape. To describe the new species *C. tsudai* as well as to reject the validity of the *Cuvierina* subgenera, Cytochrome Oxidase I mitochondrial (COI) DNA and 28S ribosomal DNA sequence data from Burrridge et al. (2015: Thesis chapter 3) were used.

RESULTS AND DISCUSSION

DISTINCTION BETWEEN *CUVIERINA TSUDAI* AND *C. PACIFICA*

Cuvierina tsudai and *C. pacifica* are similar in size but have different shell shapes, COI mtDNA and 28S rDNA. Because of their Pacific distributions and similarities in shell size, *C. tsudai* and *C. pacifica* have to date been considered the same species. Although Janssen (2005) demonstrated their presence as morphological varieties within *C. pacifica*, the congruence between morphometric and genetic differentiation supports the separation into two species (FIGURES 1A-J and 2; figure 4 in Burrridge et al., 2015: Thesis chapter 3). Shell heights of *C. tsudai* specimens are between 7.2 and 8.8 mm, showing a large overlap with *C. pacifica*, which measures between 6.6 and 8.5 mm (Janssen, 2005). However, in terms of shell shape, *C. pacifica* and *C. tsudai* are significantly different (figure 29 lower left in Janssen, 2005; Burrridge et al., 2015: Thesis chapter 3). The shell of *C. tsudai* is wider (more inflated) than the slender and more cylindrical *C. pacifica* (FIGURE 2). *Cuvierina pacifica* has a larger height/width-ratio between 3.25 and 3.96 (mean 3.50) compared to *C. tsudai*, which has a ratio between 2.77 and 3.46 (mean 3.14). The position of maximum shell width is located at 34-45% (mean 40%) of the shell height from the septum upwards for *C.*

FIGURE 1. Holotype and paratypes of *C. tsudai* and holotype of *C. pacifica*. A Holotype (RMNH.5004167) and B-I paratypes (RMNH.5004168-72) of *C. tsudai* and J holotype of *C. pacifica* (RGM 458.690) photographed in a ventral view. Photographs of RMNH.5004169-72 from Burrridge et al. (2015); RMNH.5004167-68 taken by R. van der Hulst and RGM 458.692 taken by E.F. de Vogel, this study. RMNH = Naturalis Biodiversity Center, mollusc collection and RGM = Naturalis Biodiversity Center, fossil planktonic mollusc collection, Leiden.

pacifica and at 33–42% (mean 37%) for *C. tsudai* (Janssen, 2005). The aperture of *C. tsudai* is wider, more triangular and more concave on the ventral side than in *C. pacifica*. The overall shape variation is larger for *C. tsudai* than for *C. pacifica* (FIGURE 2). The average pairwise genetic distance of COI mtDNA (658bp fragment) between *C. tsudai* ($N = 16$) and *C. pacifica* ($N = 43$) is 4.5%. The genetic variation of COI within *C. tsudai* is 1.6% compared to 0.8% within *C. pacifica*. The 28S rDNA fragment (965bp) of *C. tsudai* differs at least at one position compared with other *Cuvierina* species, except for *C. columnella* (Burrige et al., 2015: Thesis chapter 3).

The larger genetic and shell shape variation for *C. tsudai* compared to *C. pacifica* coincides with a much larger Pacific distribution and lower ecological specificity of *C. tsudai*. *Cuvierina pacifica* is restricted to the centre of the oligotrophic

FIGURE 2. Shape variation in *C. tsudai* and *C. pacifica* by means of Relative Warp (RW) data. Ordination of RW data of *C. tsudai* and *C. pacifica* for the first ventral and apertural RWs ($N = 167$ excluding one specimen with only one orientation). On the X-axis, RW1 depicts 78.26% of the total ventral shape variation. On the Y-axis, 69.43% of the apertural shape variation is explained by its RW1. Shape variations depicted by ventral and apertural RW1 (with subsequent RWs = 0) are shown.

southern Pacific gyre and occupies a more specialised ecological niche based on ecological niche modelling (ENM) than *C. tsudai* (Burrige et al., 2015: Thesis chapter 3). This study used presence-only data and six uncorrelated environmental parameters, of which ocean surface temperature and chlorophyll *a* concentration were the most important. The distribution of *C. tsudai* was mostly explained by maximum monthly sea surface temperatures (SST) and near-surface chlorophyll *a* concentrations (both 30.8%). The distribution of *C. pacifica* was best explained by low maximum monthly chlorophyll *a* concentrations (57.1%).

DESCRIPTION OF *CUVIERINA TSUDAI* SP. N.

Superfamily Cavolinioidea Gray, 1840

Family Cuvierinidae Gray, 1840

Genus *Cuvierina* Boas, 1886 (= replacement name for *Cuvieria* Rang, 1827 non Lesueur & Petit, 1807, pl. 30 (Coelenterata))

Type species. *Cuvieria columnella* Rang, 1827, p. 323, pl. 45 figures 1-3, by monotypy.

***CUVIERINA TSUDAI* SP. N.**

Cuvierina pacifica N (Janssen, 2005): Burrige et al., 2015: 5, figure 2.

Holotype. RMNH.5004167, also see FIGURE 1A and TABLE 1.

Type locality. 8°47'N, 158°49'W.

Paratypes. See FIGURE 1B-I and TABLE 1 for all specimen information. Three specimens from the type locality (RMNH.5004168); three specimens from the Zoological Museum of the University of Copenhagen, Denmark (ZMUC, not registered) illustrated by Janssen (2005, figures 18-20); five specimens from four locations (RMNH.5004169-72) studied by Burrige et al. (2015: Thesis chapter 3, referred to as *C. pacifica* N therein). The latter five specimens have COI mtDNA and 28S rDNA sequences available at GenBank (see TABLE 1).

Additional material examined. Specimens recorded as *C. pacifica* from the North Pacific Ocean in Janssen (2005: 49, 71), housed in the Muséum National d'Histoire Naturelle (MNHN, Paris, France) and ZMUC (Copenhagen, Denmark). Specimens from Burrige et al. (2015: Thesis chapter 3), referred to as *C. pacifica* N in TABLE S1 therein, with photographs deposited at the Dryad repository (DOI: 10.5061/dryad.7n1q4) and COI mtDNA (KP292730-72) and 28S rDNA sequences (KP292636-42)

deposited at GenBank. These specimens are housed in Naturalis Biodiversity Center (Leiden, The Netherlands) and ZMUC (Copenhagen, Denmark). Registration numbers, if available, from Janssen (2005).

Diagnosis. Shell moderately small, adult specimens 7.2-8.8 mm high, height/width-ratio 2.77-3.46 (mean 3.14), position of maximum shell width 33-42% (mean 37%) of shell height from septum upwards. Aperture triangular. No longitudinal micro-ornamentation.

Description. The shell shape of *Cuvierina tsudai* differs from other *Cuvierina* species. Its shell height is smaller than in *C. columnella*, *C. cancapae*, and *C. atlantica*, but larger than in *C. urceolaris*, and of similar size compared to *C. pacifica*. The position of maximum shell width is distinctly higher than for *C. columnella* and *C. atlantica* and lower than for *C. pacifica*. It is more cylindrical in shape than the inflated (bottle-shaped) *C. urceolaris* but less cylindrical than *C. atlantica* and *C. pacifica*. It differs from *C. urceolaris* and *C. cancapae* by the absence of micro-ornamentation. It has a more triangular and wider aperture than *C. urceolaris* and *C. pacifica* (FIGURE 3; Janssen, 2005; Burrige et al., 2015: Thesis chapter 3).

Distribution. *Cuvierina tsudai* has a wide, exclusively Pacific distribution between 36°N and 39°S, in which it co-exists with *C. columnella*, *C. urceolaris*, and *C. pacifica*. It has been found most often in the North Pacific, but also occurs in the South Pacific. It has not been found thus far in the central, oligotrophic parts of the South Pacific subtropical gyre, the southeast Pacific, the coral triangle west of the Philippines or southwest of Papua New Guinea.

Etymology. Named after Atsushi Tsuda, professor in biological oceanography at the University of Tokyo, Japan, for sending us pteropod samples from the Pacific Ocean and in recognition of his services to the zooplankton research community.

REJECTION OF THE SUBGENERA *CUVIERINA*

Two subgenera of *Cuvierina* were described that supposedly evolved since the early Miocene (Aquitanian, 23 million years ago): *Cuvierina s. str.*, with extant species *C. atlantica*, *C. columnella*, and *C. pacifica*, and *Urceolarica* with extant species *C. cancapae* and *C. urceolaris* (see Janssen, 2005, 2006). They were based on distinguishing shell characteristics in fossil species such as the position of maximum shell width, aperture shape and presence or absence of micro-ornamentation. However, the morphology and molecular phylogenetic information of recent species are in conflict with this separation. *Cuvierina columnella*, typically a *Cuvierina s. str.* species, has distinct micro-ornamentation, which was considered one of the distinguishing characters of the subgenus *Urceolarica*. It was shown that there are three divergent and well-supported lineages based on genetic data: the Atlantic (*C. atlantica* and *C. cancapae*), Indo-Pacific (*C. columnella*, *C. urceolaris* and *C. tsudai*), and South Pacific (*C. pacifica*) lineages (figure 4 in Burridge et al., 2015: Thesis chapter 3). Hence, we reject the two subgenera within *Cuvierina*.

TAXONOMIC KEY TO *CUVIERINA* PTEROPODS

The following taxonomic key identifies adult *Cuvierina* pteropod species based on distinctive shell shape characteristics and shell sizes. Photographs of typical adult shells are shown in FIGURE 3.

- | | | |
|---|--|----------------------|
| 1 | Micro-ornamentation present | 2 |
| – | Micro-ornamentation absent | 4 |
| 2 | Strongly inflated shell shape, shell height 5.1-6.7 mm | <i>C. urceolaris</i> |
| – | Moderately inflated or cylindrical shell shape, shell height 7.5-11.1 mm | 3 |

FIGURE 3. Typical specimens of six *Cuvierina* species.

- | | | |
|---|---|----------------------|
| 3 | Cylindrical shell shape, shell height 8.8-11.1 mm | <i>C. columnella</i> |
| – | Moderately inflated shell shape, shell height 7.5-9.3 mm | <i>C. cancapae</i> |
| 4 | Cylindrical shell shape and triangular aperture, shell height 6.7-10.5 mm | <i>C. atlantica</i> |
| – | Moderately inflated or cylindrical shell shape, triangular to kidney-shaped aperture, shell height 6.6-8.8 mm | 5 |
| 5 | Cylindrical shell shape and kidney-shaped aperture, shell height 6.6-8.5 mm | <i>C. pacifica</i> |
| – | Moderately inflated shell shape and triangular aperture, shell height 7.2-8.8 mm | <i>C. tsudai</i> |

CONCLUSIONS

Morphometric, genetic, and biogeographic information has led to the introduction of a new species of the warm water pteropod genus *Cuvierina* and the rejection of its subgenera. We encourage a combined evidence approach of taxonomy to more accurately identify species boundaries and higher taxonomic relationships in planktonic gastropods. Accurate taxonomic identification is a prerequisite to assess to what extent species are affected by ocean changes and to potentially use them as bioindicators.

ACKNOWLEDGEMENTS

We thank A. Tsuda, H. Miyamoto, E. Goetze, D. Kobayashi, L. Giuseffi, and E. Norton for contributing specimens from the Pacific Ocean, R. van der Hulst and E.F. de Vogel for photographing the holotype and some paratypes of *C. tsudai*, and J. Goud and B. van der Bijl for adding the type material to the collections of Naturalis Biodiversity Center. Finally, we are grateful to Deborah Wall-Palmer, Maria Moreno-Alcántara and Nathalie Yonow for constructive comments on this manuscript.

Assessing species boundaries in the open sea: applying an integrative taxonomic approach to a genus of pelagic molluscs

Alice K. Burridge, Remy van der Hulst,
Erica Goetze & Katja T.C.A. Peijnenburg

ABSTRACT

To track changes in pelagic biodiversity in response to ocean change, it is essential to accurately define species boundaries using integrative taxonomic methods based on diverse data types. A particularly suitable, yet challenging, group for integrative taxonomy is the pteropod genus *Diacavolinia*, shelled holoplanktonic gastropods with a circumglobal distribution. With 24 described species, they are the most speciose pteropod genus. We applied an integrative approach to assess species boundaries in this genus, with inferences based on congruence between geometric morphometric analyses of shell shape variation, genetic data (cytochrome *c* oxidase subunit I, 28S rRNA sequences), and geographic data. With observations on 969 museum and freshly-collected specimens, including holo- or paratype specimens for 14 taxa, we found evidence for a reduction in the number of described species from 24 to a maximum of 13 species. In the Atlantic Ocean, two species were well-supported in contrast to eight currently described, and in the Indo-Pacific we found a maximum of 11 species, comprising 13 of the described species. The higher species diversity in the Indo-Pacific compared to the Atlantic Ocean supports the hypothesis of an Indo-Pacific origin for *Diacavolinia* pteropods. The most important biogeographic barriers for the distribution of species were between the Atlantic and Indo-Pacific oceans, and between the East and Central Pacific. Biogeographic distributions of revised *Diacavolinia* species were as follows: Atlantic (two endemic species), warm waters south of South Africa (one endemic species), Western Indian Ocean (four species), Red Sea and Gulf of Aden (three species), Indo-West Pacific (six species, one endemic), Hawaiian waters (three species, one endemic), Sino-Japanese waters (three species), and the Eastern Tropical Pacific (three endemic species). These distributions were congruent with several well-known biogeographic provinces, and provide important information on the range of environmental variation experienced by each species. Our integrative taxonomic framework enabled more accurate assessment of species boundaries in *Diacavolinia*, a crucial step to assessing the diversity, distributions, and impact of ocean changes on these important bioindicators of ocean acidification.

This chapter is to be submitted

INTRODUCTION

Integrative taxonomy aims to rigorously delimit species and prevent under- or overestimation of species numbers by statistically testing species hypotheses with diverse, sometimes incomplete, character and data types (Edwards and Knowles, 2014; Karanovic et al., 2016). An increasing number of species is described each year as a result of the incorporation of new tools for species discovery, including virtual access to museum collections, advances in DNA sequencing, morphometric methods, and geographic information systems (Vogler and Monaghan, 2006; Knapp, 2008). Such tools have enabled integrative taxonomic approaches, in which species are described based on congruence between morphological and genetic information, with additional supporting characteristics such as behavior, ecology, or geography (McManus and Katz, 2009; Padial et al., 2010; Smith and Hendricks, 2013; Edwards and Knowles, 2014). Statistical identification of genetic lineages plays a pivotal role in species detection and satisfies multiple species concepts, because it treats species as hypotheses using objective tests (De Queiroz, 2007; Hausdorf, 2011; Morard et al., 2016). However, the usefulness of statistical approaches in the taxonomic description of species remains under debate (e.g., Bauer et al., 2011; Fujita and Leaché, 2011; Fujita et al., 2012). The sole use of genetic information in species delimitation may fail to detect the same number of species as methods that combine multiple lines of evidence (Edwards and Knowles, 2014; BurrIDGE et al., 2015: Thesis chapter 3; Karanovic et al., 2016). Species may go undetected based on a limited set of selected genetic markers, because they may be distinct only in other genes, morphology, or ecological niche space. Advances in geometric morphometric methods may especially benefit studies based on incomplete datasets, such as fossil taxa and valuable museum specimens for which genetic information could not be obtained (Karanovic et al., 2016). Developing integrative taxonomic frameworks for assessing species boundaries will enable the inclusion of museum specimens originally used to describe species combined with fresh samples for which genetic information is available.

Tracking changes in marine biodiversity in response to ocean change on a global scale requires accurate assessment of species boundaries and distributions (e.g., Goetze and Ohman, 2010; BurrIDGE et al., 2015: Thesis chapter 3; Wall-Palmer et al., 2016). Range shifts of planktonic taxa have been among the most rapid, have occurred over the largest spatial scales in comparison to other marine and terrestrial groups, and may affect higher trophic levels in the marine food web (Richardson, 2008; Beaugrand et al., 2012, 2014, 2015; Parmesan et al., 2013; Brown et al., 2016). Plankton distributions are often concordant with biogeochemical provinces at the level of species and communities (e.g., Valentin and Monteiro-Ribas, 1993; Longhurst, 1998; Reygondeau et al., 2013; Dolan et al., 2016; BurrIDGE et al., in press: Thesis chapter 6, in press: Thesis chapter 7), as well as at the level of population genetic structure within species (e.g., Norton and Goetze, 2013; Goetze et al., 2015, in press; Hirai et al., 2015). Persistent dispersal barriers may limit range shifts of some taxa in response to changing ocean conditions, while

other taxa may be able to adapt and occupy new ecological niches. Integrative taxonomy will improve the accuracy of marine species delimitation, enable the identification of rare taxa, and provide insights in current species distributions. It may be applied to a wide array of morphologically diverse marine taxa and is an essential first step to predicting species-specific ecological and evolutionary responses to ocean change, for example using Ecological Niche Modelling (Elith and Leathwick, 2009; Dambach and Rödder, 2011; Robinson et al., 2011).

Holoplanktonic gastropods are a marine group that has been identified as exceptionally vulnerable to ocean acidification (Fabry et al., 2008; Bednaršek et al., 2016). Euthecosome pteropods have aragonitic shells, and form a diverse group of organisms that are common in marine zooplankton from polar to equatorial pelagic habitats (Lalli and Gilmer, 1989). Pteropods have an extensive fossil record (Janssen, 2007a,b, 2012), and are commonly used to explore the effects of ocean acidification on marine life (Roger et al., 2011; Comeau et al., 2012; Bednaršek and Ohman, 2015; Maas et al., 2016; Moya et al., 2016). However, their usefulness as bio-indicators of the effects of ocean acidification is compromised by limited historical context for understanding species-specific long-term exposure to variations in ocean chemistry. Accurate knowledge of their taxonomy, genetic diversity, and biogeography is the essential first step to predicting ecological and evolutionary responses to ocean change.

We illustrate an integrative taxonomic approach using shelled pteropods of the genus *Diacavolinia*, which have particularly problematic systematics and are usually not identified below genus level, or are listed as *Cavolinia* sp. or *Diacavolinia longirostris* in recent studies (Jennings et al., 2010; Roger et al., 2011; Corse et al., 2013). A new taxonomic assessment of species boundaries in *Diacavolinia* pteropods is important because they are morphologically diverse, and some taxa occur in low pH regions, including the California Current coastal upwelling ecosystem (Maas et al., 2013). A study of *Diacavolinia* pteropods from Australian tropical waters found a significant increase in shell porosity along with a 10% local decline of the aragonite saturation level between the 1960s and 2000s (Roger et al., 2011), suggesting sensitivity of this taxon to contemporary changes in the ocean's aragonite saturation state.

Previously known as a single species within *Cavolinia* (*Cavolinia longirostris*), *Diacavolinia* was described as a separate genus by Van der Spoel (1987) on the basis of a distinct shell shape and shell growth compared to *Cavolinia* taxa. *Diacavolinia* is the most speciose genus of pteropods with a total of 24 extant species, of which 18 were introduced by Van der Spoel et al. (1993). Species boundaries were primarily based on shell size and small variations in shell shape that were sometimes found among sympatric taxa. *Diacavolinia* taxa occur in tropical and subtropical waters between ~17-28°C in the Atlantic, Pacific, and Indian oceans and the Red Sea, at depths of ~200 m by day and ~75 m at night across oceans (Wormelle, 1962; Van der Spoel, 1967; Bé and Gilmer, 1977). They have complex, bilaterally symmetrical shells (0.4-1.2 cm adult size), and adult shells are

easily distinguished from juveniles (Van der Spoel et al., 1993). This enables detailed geometric morphometric analyses of shell shape, which can be a very powerful tool for distinguishing taxa (Mitteroecker and Gunz, 2009; Klingenberg, 2010). Maas et al. (2013) distinguished four *Diacavolinia* species from the Northeast Atlantic and one from the Eastern Tropical Pacific based on morphological characteristics. However, they observed that Atlantic specimens were not genetically distinct (<3% divergence), whereas specimens from the Atlantic and Pacific were much more divergent (~19% divergence) based on a fragment of the cytochrome *c* oxidase subunit I mitochondrial gene (COI). The authors concluded that broader geographic sampling and a combination of genetic and morphological information were needed to resolve species boundaries in this genus (Maas et al., 2013).

We apply an integrative approach to assess species boundaries in *Diacavolinia*, with inferences based on congruence between genetic, geometric morphometric, and geographic data (FIGURE 1). To identify as many species as possible, we link datasets comprising fresh specimens for which both genetic and morphometric information is available to morphometric information from museum specimens (969 specimens), including holo- and/or paratype specimens from 14 species. We aim to (1) develop an objective method for identifying species boundaries by combining incomplete and varied datasets; (2) assess species boundaries and distribution patterns of *Diacavolinia* taxa by applying an integrative framework of genetic, morphometric, and geographic information; and (3) examine consistency of results obtained with this framework across the 24 *Diacavolinia* taxa as described by Van der Spoel et al. (1993). We find evidence to support a reduction in the number of *Diacavolinia* species, with at least eight of the species described

FIGURE 1. Schematic overview of the integrative taxonomic approach as applied to *Diacavolinia* pteropods. Distinct groups that are identified in each step are indicated. Phylogenetic position was determined based on Cytochrome *c* Oxidase I (COI) and 28S molecular markers. LDA = Linear Discriminant Analysis; PerMANOVA = non-parametric permutational multivariate analysis of variance; ABGD = Automatic Barcode Gap Discovery.

by Van der Spoel likely representing taxonomic over-splitting. We provide systematic and biogeographic descriptions of the global component of species in this complex genus.

MATERIALS AND METHODS

SPECIMENS

969 *Diacavolinia* specimens were included in this study, with collections from 152 locations between 40°N and 35°S in the Atlantic, Pacific, and Indian oceans (FIGURE 2). Of these, 263 fresh specimens suitable for genetics were obtained from 40 Atlantic, 27 Pacific, and 7 Indian Ocean locations (TABLE 1). Our fresh material was collected using plankton nets during nine oceanographic expeditions between 2001 and 2012 (TABLE S1). All fresh specimens were preserved in 96% ethanol and stored at -20°C. We also examined 706 specimens from museum collections at the Naturalis Biodiversity Center, Leiden, The Netherlands (NBC) and Zoological Museum of the University of Copenhagen, Denmark (ZMUC). These museum specimens were collected at 78 locations during ten expeditions between 1909 and 1993 and stored in 70% ethanol following initial fixation in formaldehyde (TABLE 1). Most of the museum specimens ($N = 425$) were collected during the Danish DANA expeditions between 1921 and 1932 (TABLE S1). The available museum specimens were identified by Van der Spoel et al. (1993) as 23 of the 24 described *Diacavolinia* taxa, including holo- and/or paratype specimens ($N = 79$) of 14 taxa, providing a critical link between prior and current work (TABLE S2). Specimens of *Diacavolinia robusta* were not available. Use of this historical material enabled us to make direct comparisons of species boundaries as identified by our methods versus those considered by Van der Spoel et al. (1993).

INTEGRATIVE APPROACH TO ASSESSING SPECIES BOUNDARIES

We combined genetic, geometric morphometric, and geographic observations on single *Diacavolinia* specimens wherever possible, with the approach outlined in

FIGURE 2. Geographic overview of collection locations for all *Diacavolinia* specimens used in this study, with the type of information obtained from specimens at each location.

TABLE 1. Overview of *Diacavolinia* specimens used in this study. For ventral and lateral geometric morphometrics, numbers of specimens for which morphometric data was obtained are indicated per number of landmarks (LM).

FIGURE 1. The information obtained for each specimen varied, but this framework allowed for the combination of partial observations from each specimen. Morphometric measurements consisted of a partial shell shape outline of 49 landmarks (LMs) in lateral orientation and/or 23 LMs in a ventral orientation per specimen (photographs and geometric morphometric data: SUPPLEMENTARY INFORMATION 1 and 2). For some specimens it was possible to obtain an additional 15 ventral LMs to outline the shape of the ventral lip, in cases where the soft tissue did not obscure the ventral lip (also see next paragraph; E in FIGURE 3; TABLE 1). Phylogenies were inferred from cytochrome *c* oxidase subunit I mtDNA (COI; 658 bp) and/or 28S DNA (901 bp) gene fragments (TABLE 1).

Our approach included six steps for the discovery of and assignment to species (FIGURE 1). The first step consisted of identifying integrative groups by linking genetic and morphometric information using fresh specimens ($N = 173$). To test for significant morphometric differences between genetic clades with >5 specimens, we applied non-parametric permutational multivariate analyses of variance to shell shape or size parameters (PerMANOVA based on Euclidean distances; Anderson, 2001) in Past 2.17c (Hammer et al., 2001). The PerMANOVA F -statistic was tested against 10^4 non-parametric permutations. A significantly different result provided

evidence for the presence of integrative species, with concordance observed among genetic and morphometric characters. In the second step, we examined the morphospace position of the holo- and paratype specimens identified by Van der Spoel et al. (1993), for which no genetic information is available. Geometric morphometric measurements were obtained for 79 type specimens from 14 described taxa (TABLES 1 and S2). We applied Linear Discriminant Analysis (LDA) in R 3.0.1 (R Development Core Team, 2013) to identify morphological species based on types, merge different types into a single morphological species, or merge types with integrative species as identified in Step 1. We performed separate LDAs for shape and size data of the different orientations to include as many specimens as possible and to limit the presence of correlated lateral and ventral size variables within the same LDA. Morphometric assignment criteria for synonymization with integrative groups and/or conservation of holo- and paratypes as distinct morphological species were: at least 80% confidence of belonging to a group for lateral 49 LMs, and/or 95% for ventral 23 LMs, and/or 85% for ventral 38 LMs and no contradictory assignment between orientations. These cutoff values were chosen to reflect the relatively higher information content of the shell outline of the lateral compared to the ventral orientation. If synonymized, we did so for all type specimens of the same species, based on a positively assigned majority, while also including unassigned minorities, because they were always from the same location. In this way, we reduced the number of distinct groups identified in Step 2. The third step was to identify morphological species without holo- or paratypes based on distinct positions in morphospace not covered by specimens from Steps 1 and 2, using LDA

FIGURE 3. Morphology of *Diacavolinia* shells in ventral and lateral orientations, with (A) rostrum, (B) outer hump, (C) aperture, (D) ventral lip, (E) median lip depression, (F) lock area, (G) ventral ribs, (H) spine tip, (I) spine surface, (J) gutter corner, (K) caudal joint, (L) dorsal side, and (M) maximum shell width as marked.

to justify this distinction. The fourth step was the LDA assignment of the remaining specimens for which morphometric information was available to the groups identified in Steps 1-3. Remaining specimens were either non-sequenced fresh or non-type specimens from museum collections. Individuals remained unidentified if they did not meet the assignment criteria or were assigned ambiguously between orientations. In the fifth step, we identified possible species based on individuals with genetic, but without morphometric information. These are treated as separate groups because their genetic data could not be linked to morphological data from other groups, although they may be synonymous to groups identified in Steps 2-3. Finally, in the sixth step, we plot sampling locations of all identified species and possible species of *Diacavolinia*.

GEOMETRIC MORPHOMETRICS

For quantitative analyses of *Diacavolinia* shell shapes and sizes, fresh and museum specimens were photographed in lateral ($N = 904$) and ventral ($N = 919$) orientations using a Nikon D100 6 mpx camera (Micro-Nikkor lens 55 mm / 3.5, aperture $f / 11$, shutter speed 1 / 1.3s, ISO 200, fixed zoom) attached to a stand. To standardize the ventral orientation, specimens were mounted on photographic film using 60% methyl glucose. For lateral standardization we used fine black sand, free from organic material. For geometric morphometric analyses, we selected photographs of all fully developed adults and excluded specimens that were not well-focused or in standard orientation. We also excluded specimens that were damaged or obscured at relevant positions by soft tissue that could not be removed without damaging the shell. Selected photographs were compiled for further analysis using tpsUtil software (Rohlf, 2006).

We used a combination of landmarks and semi-landmarks for partially outlining shell shapes in tpsDig (Rohlf, 2006) to cover as much shell shape variation as possible for as many specimens as possible (Gunz and Mitteroecker, 2013). To assess the shape variation in the laterally photographed shells, two partial outlines were created, which were connected at the caudal joint between its ventral and dorsal parts at the bottom of the shell (also see FIGURE 3 for shell anatomy). The first partial outline started at the position of maximum width of the ventral part, ended at the caudal joint and was standardized per specimen to 15 LMs separated by equal length. The second partial outline started at the top of the shell rostrum, ended at the caudal joint via the dorsal part of the shell and was standardized to 35 LMs. Because of the mutual landmark at the caudal joint, this resulted in a total lateral outline of 49 LMs. Creating the first partial outline of 15 LMs was possible for 752 specimens and creating both (49 LMs) was possible for a subset of 549 specimens (TABLE 1). To assess shape variation in a ventral orientation, two LMs were placed at the left and right gutter corners and a third LM was placed at the caudal joint. Subsequently, left and right partial outlines of 10 LMs each were generated from the lock areas left and right of the shell aperture downwards to the closest position without overlap between ventral and dorsal shell parts, the upper start of the dorsal spine surface (also see FIGURE 3). This resulted in a total of 23 LMs

for 646 specimens. No landmarks were created on the two spine tips because these were often damaged. For a subset of 314 specimens it was possible to create an additional 15 LM outline of the ventral lip, resulting in a total of 38 LMs.

We used tpsRelw software (Rohlf, 2006) to rotate, translate, and scale LM coordinates through generalized least-square Procrustes superimposition (GLS; Kendall, 1977). This provided centroid sizes, a size measure depending on the surface area within all LMs, and multiple relative warp (RW) axes containing information on shape variation, with the first RW containing most information. The morphospace of the lateral orientation was represented by 26 relative warps (RWs) for 15 LMs and 94 RWs for 49 LMs. In ventral orientation, there were 42 RWs for 23 LMs and 72 RWs for 38 LMs.

To test for repeatability of RWs, a selection of 19 museum specimens was photographed in two subsequent series for lateral 15 LMs and 49 LMs and ventral 23 LMs, of which 10 could also be used for ventral 38 LMs. Intra-class correlation coefficients (ICCs) between the two series were calculated for the centroid sizes and first 10 RWs in Past 3.0 (Hammer et al., 2001). RWs were considered repeatable when ICC > 0.80, and only repeatable RWs were used in further analyses of shell shape. Centroid sizes were always repeatable (ICC > 0.99). For 15 LMs, the first two RWs were repeatable (ICC > 0.94) and contained 95.96% of the shape variation for this part of the shell. For 49 LMs, RWs 1-8 and 10 were repeatable (ICC > 0.91), accounting for 98.29% of the shell shape variation. In a ventral orientation, repeatable RWs for 23 LMs were 1-5 and 8 (ICC > 0.83; 92.36% of shape variation) and 1-5 (ICC > 0.81; 83.17%) for 38 LMs, respectively.

GENETICS

To assess genetic diversity and phylogenetic relationships within *Diacavolinia*, we obtained 86 COI mtDNA (GenBank accession numbers MF974762-MF974847) and 138 28S DNA (GenBank accession numbers MF974624-MF974761) sequences from a total of 173 specimens, following photography of shells of the same individuals for morphometric measurements. Tissue fragments of one mm³ for DNA extraction could only be obtained by damaging the shells. DNA extraction was performed using the EZNA Mollusc DNA Kit (Omega Biotek 2013), as recommended by Maas et al. (2013). We followed the manufacturer's recommended methods without freeze-drying of tissue before DNA extraction.

A 658 bp fragment of COI was amplified using the primers LCO1490 (5'-GGTCA ACAAATCATAAAGATATTGG-3') and HCO2198 (5'-TAAACTTCAGGGTGACCAAAAAT CA-3'; Folmer et al., 1994). Reactions were run in 25 µl volumes consisting of 15.75 µl MilliQ, 2.5 µl 10x PCR buffer containing 1.5 mM MgCl₂ (Qiagen), 0.5 µl MgCl₂ (25 mM), 2.0 µl dNTPs (2.5 mM per nucleotide), 0.25 µl Taq (Qiagen), 1.0 µl (10 mM) of each primer, and 2.0 µl DNA template. A 901 bp fragment of the nuclear 28S ribosomal gene was amplified using the primers 28SC1F (5'-ACCCGCTGAATTTAAG CAT-3') and 28SD3R (5'-GACGATCGATTTGCACGTCA-3'; Dayrat et al., 2001). The 25 µl reaction consisted of 15.25 µl MilliQ, 2.5 µl 10x PCR buffer containing 1.5 mM

MgCl₂ (Qiagen), 0.5 µl MgCl₂ (25 mM), 2.5 µl dNTPs (2.5 mM per nucleotide), 0.25 µl Taq polymerase (Qiagen), 1.0 µl (10 mM) of each primer, and 2.0 µl DNA template. PCR was performed applying an initial denaturation of 4 min at 94°C, 35 cycles of 1 min at 94°C, 30 s at 50°C, 1 min at 72°C and finally 5 min at 72°C for final extension, followed by ~1 h at 12°C. If the initial PCR failed, an anti-inhibitor treatment (PCR Inhibition Removal Kit, Zymo Research, USA) was applied. Sanger sequencing of PCR products was performed using an ABI3730XL sequencer (Life Technologies; outsourced to BaseClear, Leiden, The Netherlands).

Forward and reverse COI and 28S sequences were assembled in MEGA 6.0 (Tamura et al., 2013) and CodonCode Aligner 4.1 (CodonCode Corporation, USA, 2013). For 28S, double peaks were registered as ambiguous when apparent in both forward and reverse sequences and with a secondary peak that was at least 1/3 of the height of the primary peak. Assembled sequences were aligned using the MAFFT algorithm (MAFFT version 7) and their identities as shelled pteropods were checked by BLAST against the NCBI nt database (Altschul et al., 1997). Three Pacific *Diacavolinia* sequences from Maas et al. (2013; GenBank accession numbers JX183614-JX183616) were included in the COI alignment, as well as two Atlantic and two Pacific *Cavolinia uncinata* specimens (Burr ridge et al., 2017: Thesis chapter 2; GenBank accession numbers MF048915-MF048918 for COI and MF048968-MF048971 for 28S) in both alignments.

Maximum Likelihood (ML; Felsenstein, 1981) was used to infer phylogenetic relationships among specimens for both the COI and 28S alignments. For COI, we used a General Time Reversible (GTR) substitution model with different evolutionary rates for the three codon positions (CP), because this is a biologically realistic model for protein coding sequences (Shapiro et al., 2006). GTR with a proportion of invariable sites (I) and gamma distributed rate variation among sites (Γ) was selected from 24 models using the Akaike Information Criterion (AIC) in JModeltest 2.1.7, in which CP-models were not available (Darriba et al., 2012). For 28S, the most appropriate substitution model selected using AIC was GTR + I. Molecular phylogenies were inferred using Maximum Likelihood followed by non-parametric bootstrap analyses with 1000 bootstraps in RaxMLGUI 1.3 (Stamatakis, 2006; Silvestro and Michalak, 2012).

To quantify differences between and within genetic clades, we calculated pairwise genetic distances between COI haplotypes as well as 28S alleles using the K2P + Γ distance model of evolution that assumes equal evolutionary rates among all transitions as well as among all transversions (Kimura, 1980) in MEGA 6.0 (Tamura et al., 2013). Among the available models in MEGA 6.0, this model most closely represented our sequence data according to the AIC for COI and 28S. We reconstructed alleles from 28S genotypes using the PHASE algorithm (Stephens et al., 2001; Stephens and Donnelly, 2003) in DnaSP v5 (Librado et al., 2009).

We first identified molecular operational taxonomic units (MOTUs) based on COI and 28S sequences separately, using the online version of ABGD (Automatic Barcode Gap Discovery; Puillandre et al., 2012). Subsequently, integrative species

were defined based on a pairwise genetic distance of at least 5% divergence for COI, combined with the ability to distinguish groups morphologically using geometric morphometric methods. If COI sequences were not available, additional groups were identified based on the presence of unique 28S mutations. If morphologies between different MOTUs could not be distinguished, they were treated as a single group.

RESULTS

INTEGRATIVE APPROACH TO ASSESSING SPECIES BOUNDARIES

Geometric morphometric data demonstrate large variation in shell sizes and shapes among *Diacavolinia* specimens, especially in the Indo-Pacific (FIGURES 3-5 and S1). The first three lateral RWs captured 43.38, 21.95, and 14.97% of the total shell shape variation, respectively (FIGURES 4 and S1A). For ventral RWs (23 LMs) these results were 43.38, 27.20, and 10.79% (FIGURES 5A,B and S1B).

There were 251 polymorphic sites in the COI nucleotide alignment of *Diacavolinia* ($N = 89$; 658 bp; GenBank accession numbers MF974762-MF974847). For 28S ($N = 138$; 901 bp; GenBank accession numbers MF974624-MF974761) there were 28 polymorphic sites of which 10 contained ambiguous base assignments, all based on transitions of C-T (Y) and A-G (R).

STEP 1: IDENTIFICATION OF INTEGRATIVE SPECIES

We identified six integrative species based on combined genetic and geometric morphometric information on fresh specimens in step 1: Groups 1 (Atlantic), 3-5 (Indo-Pacific), 6 (Pacific), and 7 (Indian Ocean; FIGURE 6; groups numbered sequentially for Atlantic followed by Indo-Pacific throughout). The COI phylogeny included Groups 1 ($N = 56$; 1 MOTU), 3 ($N = 21$; 1 MOTU), 5 ($N = 6$; 2 MOTUs), 6 ($N = 1$; 1 MOTU), and 7 ($N = 1$; 1 MOTU; FIGURE 6A). For Group 4, COI sequences failed to amplify in PCR. Groups 12 and 13, for which we obtained COI sequences but lack morphological data, are discussed in Step 5. Pairwise genetic distances of COI haplotypes between these groups were high with averages of 18.6-43.8% (TABLE S3). Pairwise distances were small within Groups 1 (average 1.4%, range 0-2.7%) and 3 (0.4%, 0-1.1%), and larger within Group 5 (6.3%, 0.5-15.6%). Within Group 5, a single specimen was assigned to a different MOTU based on COI sequences, but because no geometric morphometric differences could be detected it was not treated as a separate group. Without this specimen, pairwise distances within Group 5 were 2.0% (0.5-3.0%). The Atlantic COI sequences from Maas et al. (2013) all corresponded to Group 1 (NCBI BLAST-search; not included in counts or analyses). Other groups with COI sequences but without morphological data are discussed in Step 5. The 28S phylogeny included Groups 1 ($N = 35$), 3 ($N = 17$), 4 ($N = 78$), 5 ($N = 6$), 6 ($N = 1$), and 7 ($N = 1$) and no additional groups without morphological data were identified based on this genetic marker. Two well-supported *Diacavolinia* clades were present, each representing one 28S MOTU as identified by ABGD (FIGURE 6B). The first clade contained Groups 1, 3, 6, and 7 ($N = 54$) from all three

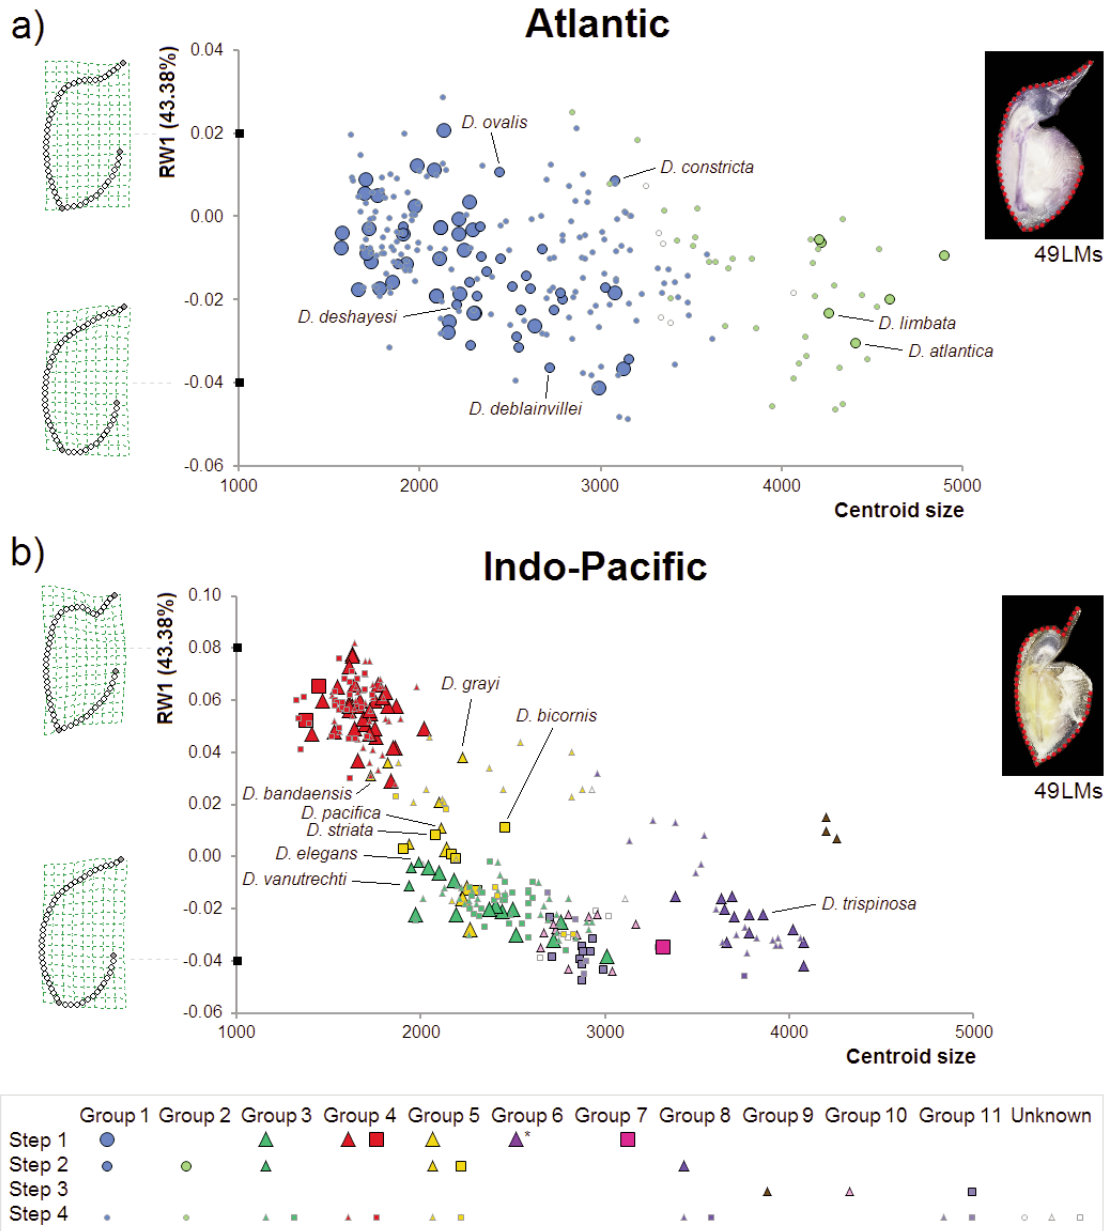

FIGURE 4. Ordination of centroid sizes and the first Relative Warp (RW) axis of *Diacavolinia* in a lateral orientation with 49 landmarks (LMs) for (A) Atlantic specimens and (B) Indo-Pacific specimens. The morphospace positions are indicated as circles for Atlantic ($N = 267$), triangles for Pacific ($N = 190$), and squares for Indian Ocean ($N = 92$) specimens. Colors indicate distinct groups. Symbol sizes represent the steps in the integrative taxonomic approach in which specimens were assigned to a group (see legend). Corresponding thin plate splines of the most positive and negative deformations are indicated along RW1 to depict the variation in shell shape, with images of shells and LM positions shown on the right. Names of holotypes, and if not available, representative paratypes, are indicated. Groups 12 and 13 are not shown because no morphological data was available.

FIGURE 5. Ordination of centroid sizes and the first Relative Warp (RW) axis of *Diacavolinia* in a ventral orientation for (A) Atlantic specimens with 23 landmarks (LMs, $N = 268$), (B) Indo-Pacific specimens with 23 LMs ($N = 378$), and (C) a subset of Indo-Pacific specimens with 38 LMs ($N = 174$). See FIGURE 4 for symbol definitions. Corresponding thin plate splines of the most positive and negative deformations are indicated along RW1 to depict the variation in shell shape, with shell image and LM positions shown on the right. Names of holotypes, and if not available, representative paratypes, are indicated.

FIGURE 6. Maximum likelihood trees of (A) cytochrome *c* oxidase I (COI) mtDNA sequences ($N = 89$) and (B) nuclear 28S rDNA sequences ($N = 138$) of *Diacavolinia*. The COI phylogeny (A) includes Groups 1 ($N = 56$), 3 ($N = 21$), 5 ($N = 6$), 6 ($N = 1$), 7 ($N = 1$), 12 ($N = 3$, from Maas et al., 2013; GenBank accession numbers JX183614-JX183616; Pacific Ocean), and 13 ($N = 1$). The 28S phylogeny (B) includes Groups 1 ($N = 35$), 3 ($N = 17$), 4 ($N = 78$), 5 ($N = 6$), 6 ($N = 1$), and 7 ($N = 1$). Four *Cavolinia uncinata* outgroup sequences are included to root each tree (Genbank accession numbers MF048915-MF048918 for COI and MF048968-MF048971 for 28S from BurrIDGE et al., 2017: Thesis chapter 2). Numbers indicate bootstrap support in ML analyses (only bootstrap values ≥ 90 are shown). Colors indicate distinct genetic groups; symbols indicate rare genetic groups (triangle = Pacific; square = Indian Ocean). Not all groups were amplified in PCR for both markers.

oceans. The second clade consisted of Groups 4 and 5 ($N = 84$) and was restricted to the Indo-Pacific. The average genetic distance between alleles of the two clades was 2.4% (1.7-3.0%). Within the first clade, this was 0.2% (0-0.6%), and within the second clade it was 0.1% (0-0.4%). The groups within the first clade could not unequivocally be distinguished from one another based on 28S alone. Groups 4 and 5 within the second clade could always be distinguished from each other (0.3%, 0.2-0.4% genetic distance between alleles; TABLE S3).

Geometric morphometric and genetic data were congruent for the integrative species identified (FIGURES 4-6 and S1). Across all orientations, LDA demonstrated a 100% correspondence between geometric morphometric and genetic data for Groups 1 and 5. Accuracy was 92.9% for Group 3 and 95.9% for Group 4, with the remaining individuals not reaching the assignment criteria for unambiguous identification (TABLE S4). We obtained geometric morphometric measurements of shell shape and size for 112 sequenced individuals with $N = 89$ for lateral 49 LMs, $N = 94$ for ventral 23 LMs, and $N = 57$ for ventral 38 LMs (TABLE S1). The shell shapes of Groups 1 and 3-5 were significantly different in all orientations (Bonferroni-corrected $p < 0.001$ for all orientations; $F = 45.84$ for lateral 49 LMs; $F = 17.49$ for ventral 23 LMs; $F = 17.69$ for ventral 38 LMs). Some, but not all shell sizes were significantly different based on centroid size measurements. For lateral 49 LMs, Group 4 was significantly smaller than Groups 1, 3, and 5 ($p < 0.001$, 0.001, and 0.01; $F = 36.75$, 127.1, and 59.15, respectively). The same was true for 38 LMs ($p < 0.05$, 0.01, and 0.01; $F = 8.217$, 31.74, and 35.23, same order) and for ventral 23 LMs ($p < 0.001$ for all combinations; $F = 27.04$, 75.07, and 48.57). Additionally, Group 1 was significantly smaller than Group 3 in this orientation ($p < 0.01$; $F = 9.318$).

STEP 2: IDENTIFICATION OF MORPHOLOGICAL SPECIES WITH HOLO- AND PARATYPES

In the Atlantic Ocean, holo- and paratypes of *D. atlantica* and *D. limbata africana* were identified as Group 2 with 100% confidence. Holo- and paratypes of *D. deblainvillei*, *D. deshayesi*, *D. constricta*, and *D. ovalis* were placed into Group 1 with a confidence of 96.4% (FIGURES 1, 4A and 5A; TABLE S4). We did not use the ventral orientation with 38 LMs for identifying Atlantic specimens because this part of the shell was always obscured by soft tissue for Group 2.

In the Pacific Ocean, *D. triangulata* holo- and paratypes were identified as Group 8 with 100% confidence. Based on geometric morphometric data from the Indo-Pacific, seven taxa were placed into groups from Step 1 (FIGURES 1, 4B, 5B,C and S1; TABLE S4). *Diacavolinia elegans* and *D. vanutrechtii vanutrechtii* paratypes from the Pacific fit into Group 3 (75% confidence). The Pacific *D. grayi*, *D. bandaensis*, and *D. pacifica* holo- and paratypes as well as the Indian Ocean *D. striata* and *D. bicornis* paratypes were identified as belonging to Group 5 (64% confidence). The higher fraction of ambiguous type specimens in Group 5 may be due to the relatively large morphospace covered by this group, in which we could not distin-

guish any subgroups, and for which at least two MOTUs were identified by ABGD based on COI sequences.

STEP 3: IDENTIFICATION OF MORPHOLOGICAL SPECIES WITHOUT TYPES

We distinguished three additional morphological species based on the morphospace position of non-type museum specimens from the Indo-Pacific (Groups 9-11; $N = 26$; FIGURES 1, 4B, 5B,C and S1). For all three groups, there was a 100% correspondence between their estimated position in morphospace and their LDA assignment (TABLE S4). Non-type specimens were previously identified by Van der Spoel et al. (1993) as Pacific *D. strangulata* (Group 9), Pacific *D. mcgowani* and *D. longirostris* (Group 10), and *D. longirostris* from the Indian Ocean (Group 11). Group 9 was distinguished by a strongly ventrally directed shell rostrum and large size, Group 10 was identified by large spines and a triangular appearance in a ventral orientation, and Group 11 was recognized by a subtle outer hump combined with a ventrally directed shell rostrum.

STEP 4: ASSIGNMENT OF REMAINING SPECIMENS TO MORPHOGROUPS

Of our fresh specimens with morphometric but without genetic data, all Atlantic specimens ($N = 33$) were assigned to Group 1 by LDA. Pacific specimens ($N = 15$; 94.8%) were assigned to Group 4 (1 specimen was ambiguous). We thus infer that a representative number of specimens from Groups 1 and 4 were sequenced in Step 1. Of our remaining museum specimens, 423 specimens (88%) were successfully assigned to groups, and 58 (12%) were not (TABLE S4).

STEP 5: IDENTIFICATION OF POSSIBLE SPECIES

Two additional groups were identified based on COI sequences alone, each representing one MOTU (Groups 12 and 13; FIGURE 6A; TABLE S4). Group 12 contained all three Eastern Tropical Pacific sequences from Maas et al. (2013; listed as *D. vanu-trechti*). Group 13 contained a single sequence from the Indian Ocean near South Africa and its phylogenetic position was between other *Diacavolinia* groups and *Cavolinia uncinata*. No morphological information was available for these groups because Group 12 was solely represented by sequences from Maas et al. (2013) and Group 13 was represented by a single juvenile specimen with a damaged shell.

STEP 6: GLOBAL BIOGEOGRAPHY

Biogeographic ranges of the identified groups were diverse and varied in size (FIGURE 7). In the Atlantic ocean, two groups occur: Group 1 ($N = 276$) is present across the entire range (39°N-26°S) including the Caribbean Sea and Group 2 ($N = 51$) is found only in the northern hemisphere and predominantly around the Azores, near the Cape Verde Islands, and in the Gulf of Guinea. Groups 3-5 are the most common groups in the Indo-Pacific ($N = 100$; 172; 64), and they all have wide Indo-Pacific distributions. Less common are Group 8 ($N = 49$), predominantly occurring in the central Indo-Pacific but also extending west to the Red Sea, and Group 11 ($N = 19$) from the southern part of the central Indo-Pacific and in and near the Gulf of Aden. Of the remaining, rare groups, Group 6 ($N = 1$) is found

south of Hawaii at 14°N and Groups 9 ($N = 3$), 10 ($N = 12$), and 12 ($N = 3$) all occur in the Eastern Tropical Pacific (ETP), of which Group 10 ($N = 12$) was sampled near the coast of Panama. Groups 7 and 13 were each found once in the Indian Ocean, with Group 7 occurring close to the Cocos-Keeling Islands and Group 13 occurring in warm waters near South Africa (FIGURE 7).

SYNTHESIS

Following our integrative approach, a total of 752 specimens (77.6% of 969 available specimens) were assigned to 13 groups (FIGURES 1 and 8; TABLE S4). We distinguished two groups in the Atlantic Ocean and 11 groups in the Indo-Pacific. We

FIGURE 7. Distribution of *Diacavolinia* groups 1-13 as identified in this study. A presence record was mapped if at least one specimen from that locality was positively identified. Group # numbers are indicated at the top of each map.

consider there to be sufficient genetic and morphometric evidence for the validity of the Atlantic Group 1 and Indo-Pacific Groups 3-5 as integrative species, with possible additional diversity within Group 5. Although we had only one specimen each for Groups 6 and 7, they likely also represent separate species based on genetic and morphometric data. We identified Atlantic Group 2 and Indo-Pacific Groups 8-11 as morphological species, but they were not sampled in our recent collection and we lack genetic information for these taxa. Hence, we could not link them to possible species of Groups 12 and 13, for which we only had genetic information. We consider it, however, unlikely that Group 13 represents any morphological species based on its South African locality with none of Groups 8-11 occurring nearby. Of the unassigned individuals ($N = 217$), 158 specimens provided no evi-

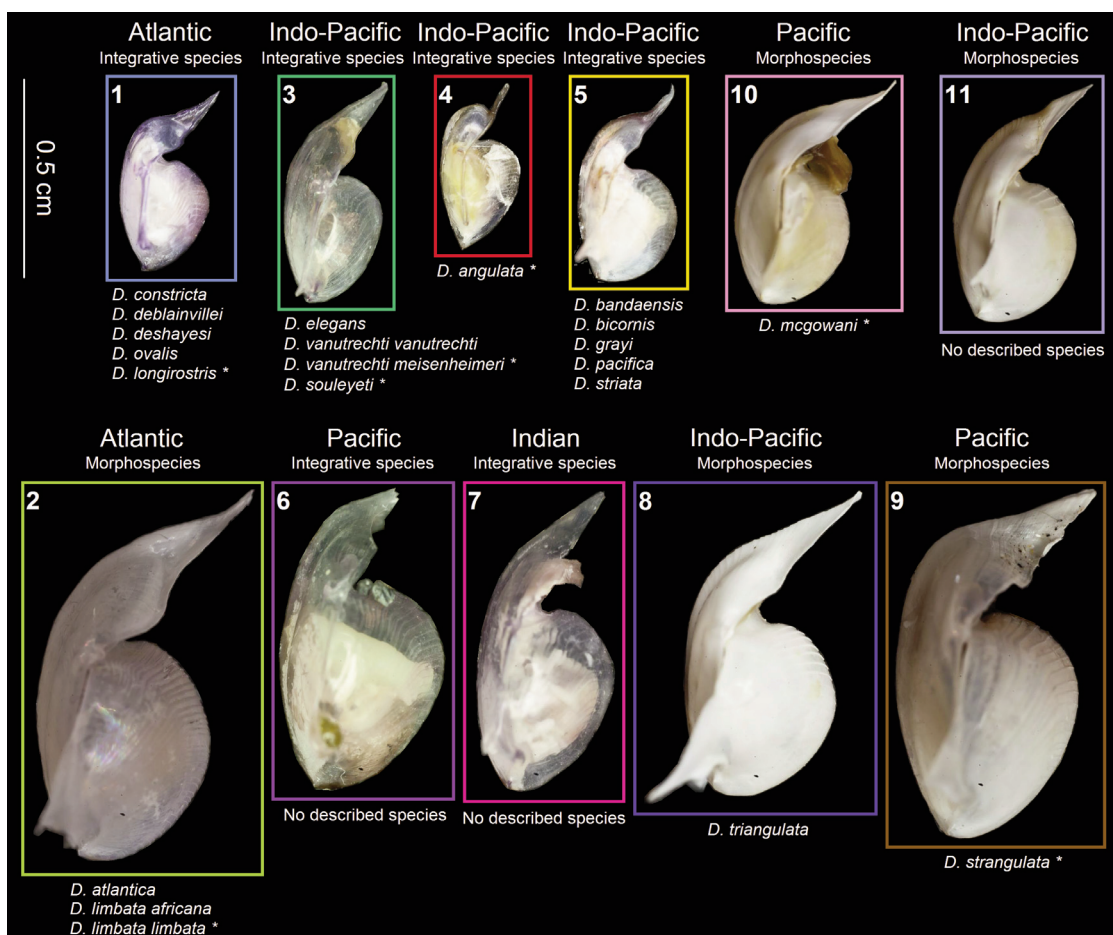

FIGURE 8. Overview of *Diacavolinia* revised taxonomy with example specimens of groups 1-11 shown in a lateral orientation. Species names as (re)described by Van der Spoel et al. (1993) are listed below each group based on holo- and paratype specimens. For species with an (*) no type specimens were included in this study, but they are listed below the group to which the majority of specimens identified as such was assigned in Steps 3 and 4, and are listed only if the species was originally described from the same ocean basin. Photo sizes are standardized to the 0.5-cm scale bar. Groups 12 and 13 are not shown because no morphological data was available.

dence to either determine their position in morphospace (no photographs, or unusable photographs), or to determine their molecular phylogenetic position. A further 59 specimens for which geometric morphometric measurements were available, of which 50 from the Indo-Pacific, could not be confidently assigned to a group and may represent additional diversity.

FIGURE 8 gives an overview of typical adult shell shapes (in lateral orientation) and sizes for Groups 1-11. Important morphological characteristics for distinguishing between *Diacavolinia* species are the presence of an outer hump (B in FIGURE 3), direction of the shell rostrum (A in FIGURE 3) and spines (H in FIGURE 3) relative to the rest of the shell, convexity of the dorsal (L in FIGURE 3) and ventral parts as seen in lateral orientation, and shell size.

DISCUSSION

INTEGRATIVE TAXONOMY AND PTEROPOD DIVERSITY

To our knowledge, this is the first time a global collection of samples, including recent and museum type specimens of a marine zooplankton group, have been combined into a single dataset for integrative taxonomic purposes. We successfully linked 969 specimens belonging to the pteropod genus *Diacavolinia* for which there was morphological and/or genetic information available. Using museum material also used by Van der Spoel et al. (1993) allowed for direct comparison with previous taxonomies. In this way, we more accurately and objectively resolved species boundaries and species distributions than has been possible in prior work.

Our findings suggest that the 24 taxa described by Van der Spoel et al. (1993) should be reduced to a maximum of 13 species. Especially in the Atlantic Ocean, the number of species should be reduced from eight to two, with one species comprising *D. constricta*, *D. deblainvillei*, *D. deshayesi*, *D. ovalis*, and *D. longirostis*, and the other comprising *D. atlantica*, *D. limbata africana*, and *D. limbata limbata* (FIGURE 8). New taxonomic descriptions should reflect the larger morphological variation covered by each group. Although the overall morphological diversity in the Atlantic was large, we found little structure in our morphometric data and low levels of genetic diversity, in contrast to the Indo-Pacific. In the Indo-Pacific, we found a maximum of 11 species, comprising 13 of the original taxa described by Van der Spoel et al. (1993). Based on our findings, *D. angulata*, *D. triangulata*, *D. strangulata*, and *D. mcgowani* are confirmed as valid species. Nine original taxa should be merged into two species: one species comprising *D. elegans*, *D. vanutrechtii vanutrechtii*, *D. vanutrechtii meisenheimeri*, and *D. souleyeti*, and one comprising *D. bandaensis*, *D. bicornis*, *D. grayi*, *D. pacifica*, and *D. striata*. The latter species may comprise additional unresolved diversity. Furthermore, three Indo-Pacific groups identified in this study require taxonomic names (FIGURE 8). Despite the global distribution of our samples, some taxonomic uncertainties remain, especially in the Indo-Pacific, Eastern Tropical Pacific (ETP), and Red Sea. The sampling coverage in the Atlantic Ocean was higher than in the Indo-Pacific. The species status of three original,

described taxa remains unknown: *D. aspina*, *D. robusta*, and *D. flexipes*, described from the Indian Ocean, Pacific Ocean, and Red Sea, respectively (Van der Spoel et al., 1993). We failed to assign non-type material identified as *D. aspina* ($N = 1$) by Van der Spoel et al. (1993) to any group unambiguously and did not have *D. robusta* specimens available. Finally, we did not have the type material nor other material identified as *D. flexipes* from the Red Sea. However, Janssen (2007b) suggested that the species status of *D. flexipes* based on subtle morphological differences is doubtful, and rather represents intraspecific variation.

The higher overall species diversity in the Indo-Pacific compared to the Atlantic supports the hypothesis of an Indo-Pacific origin for *Diacavolinia* as outlined in Van der Spoel et al. (1993). *Diacavolinia* was already present in the Indo-Pacific in the Pliocene (Piacenzian, 3.6-2.6 million years ago (mya)), based on fossils from northern Philippine sediments described as *Diacavolinia pristina* (Janssen, 2007a). It is unknown how long *Diacavolinia* has been present in the Atlantic Ocean. The ratio between the number of *Diacavolinia* species found in the Atlantic versus the Indo-Pacific is 0.18 based on our integrative analysis compared to 0.7 in previous research (Van der Spoel et al., 1993). Members of other, older euthecosome genera than *Diacavolinia* may have been able to disperse more easily at (sub)tropical latitudes at their times of origin, because the Isthmus of Panama and Tethys Sea were still open (closing at ~3.5 and ~13.5 mya, respectively; Bowen et al., 2016). Atlantic:Indo-Pacific species ratios of other genera appear to increase with time of origin (data from Checchia-Rispoli, 1921; Scarsella, 1934; Bernasconi and Robba, 1982; Janssen, 1990, 2005, 2006, 2007a; Cahuzac and Janssen, 2010; Burrige et al., 2015: Thesis chapter 3, 2016: Thesis chapter 4; Bowen et al., 2016; World Register of Marine Species (WoRMS)). When only considering extant, epipelagic, warm water species, ratios of straight-shelled genera (Cavolinioidea) containing more than one such species are 0.43 for *Diacria* (Miocene: Tortonian, 7.2-11.6 mya), 0.5 for *Cuvierina* (Miocene: Aquitanian, 20.4-23 mya), 0.67 for *Cavolinia* (Miocene: Langhian, 13.8-16 mya), 0.75 for *Clio* (Eocene: Priabonian, 33.9-38.0 mya), and 1 for *Creseis* (Eocene: Bartonian, 38-41 mya). *Creseis* is the oldest extant straight-shelled genus. All epipelagic, warm water species of the coiled genera *Limacina* and *Heliconoides* (Limacinoidea) also appear to have circumglobal distributions and Atlantic:Indo-Pacific species ratios of 1, with the first representative being described from the Late Cretaceous: Campanian (83.5-72.1 mya; Janssen and Goedert, 2016). These observations suggest an increased Atlantic:Indo-Pacific species ratio for pteropod genera with a longer evolutionary history.

BARRIERS TO DISPERSAL

Persistent dispersal barriers may limit range shifts of some taxa in response to changing ocean conditions, while other taxa may be able to adapt and occupy new ecological niches. The most important biogeographic barriers for *Diacavolinia*, as inferred from distinct species assemblages, were between the Atlantic and Indo-Pacific oceans and the East and Central Pacific. Biogeographic distributions of

revised *Diacavolinia* species were as follows: Atlantic (two endemic species), warm waters south of South Africa (one endemic species), Western Indian Ocean (four species), Red Sea and Gulf of Aden (three species), Indo-West Pacific (six species, one endemic), Hawaiian waters (three species, one endemic), Sino-Japanese waters (three species), and Eastern Tropical Pacific (three endemic species). Species distributions were less patchy and disjunct compared to Van der Spoel et al. (1993) and may better reflect ecological and/or habitat preferences of *Diacavolinia* taxa. The distribution patterns of the revised *Diacavolinia* species were congruent with several well-known biogeographic provinces for other holoplankton or benthic species with pelagic larvae, and provide important information on the range of environmental variation experienced by each species (e.g., Kulbicki et al., 2013; Bowen et al., 2016; Iacchei et al., 2016). Kitidis (in press) observed evidence of ocean acidification along a longitudinal transect across the Atlantic Ocean, and estimated an annual rate of pH decrease of 0.0013 ± 0.0009 units. Jiang et al. (2015) observed that the aragonite saturation depth was deeper in the North and South Atlantic (~1000-2500 m), South Indian (~750-1500 m), and Southwest Pacific Ocean (~500-1500 m) compared to the North Indian (350-600 m), North Pacific (~200-750 m), and Southeast Pacific Ocean (~150-500 m). They also observed that in the Atlantic and Pacific oceans the aragonite saturation state in waters shallower than 100 m depth decreased by ~0.40% on average from the decade spanning 1989-1998 to the decade spanning 1998-2010. These findings suggest that *Diacavolinia* species in the East Pacific, the endemic Groups 9, 10, and 12, may be more exposed and vulnerable to future ocean acidification than other *Diacavolinia* species.

The Agulhas Current in the Indian Ocean intermittently forces warm eddies into the Atlantic (Hutchings et al., 2009; Villar et al., 2015). Although distributions of two *Diacavolinia* taxa extended to waters south of South Africa, we did not find evidence for recent dispersal among the Atlantic and Indian Oceans along this pathway. Hence, the degree of connection of *Diacavolinia* in the Atlantic and Indo-Pacific basins appears to have been overestimated by Van der Spoel et al. (1993), who reported that five of the 24 originally described *Diacavolinia* taxa occurred in both the Atlantic and the Indo-Pacific. For *Cuvierina* pteropods, also no evidence of recent dispersal from the Indian Ocean into the Atlantic Ocean was found (Janssen, 2005; Burrige et al., 2015: Thesis chapter 3). More rigorous molecular examination of other warm-water euthecosomes may identify higher numbers of endemic species in the Atlantic and Indo-Pacific ocean basins than have been described to date. Other pelagic examples for which Atlantic taxa are isolated from the Indo-Pacific include several copepods (e.g., Hirai et al., 2015; Goetze, 2011) and populations of two-wing flyfish (Lewallen et al., 2016). Conversely, evidence of Agulhas leakage among ocean basins has increased over the last decade (Blastoch et al., 2009). Sporadic dispersal through Agulhas rings has been demonstrated, e.g., for moray eels and glass-eye fish (Reece et al., 2010; Gaither et al., 2015). Additionally, Villar (2015) demonstrated an overlap in metabarcode MOTUs of the plankton community within Agulhas rings between the Indian and South Atlantic oceans.

We found evidence for endemism of *Diacavolinia* species in the Eastern Tropical Pacific (ETP). Other genetic studies of East Pacific plankton showed that some, but not all taxa demonstrated East Pacific endemism, and it is likely that cryptic diversity is present within what are now considered single species or species complexes. Within another group of planktonic gastropods (heteropods, Pterotracheoidea), *Atlanta californiensis* is restricted to the East Pacific (Seapy et al., 2003). Some endemic cryptic diversity within the ETP also was found in the *Pleuromamma piseki* – *P. gracilis* copepod species complex (Halbert et al., 2013). Taxa with pelagic larval stages sometimes demonstrated East Pacific isolation, such as the reef-building coral *Porites lobata* (Baums et al., 2012) and the spiny lobster *Panulirus penicillatus* (Iacchei et al., 2016), but not always, such as the echinoderm *Echinothrix diadema* (Lessios et al., 1998).

Red Sea endemism appears to have multiple causes, with a cold, nutrient-rich barrier separating the Gulf of Aden from the rest of the Arabian Sea, and a narrow strait separating the Red Sea from the Gulf of Aden. Moreover, circulation patterns and environmental gradients may provide additional isolating barriers to dispersal (DiBattista et al., 2016). We found indications for isolation of Red Sea fauna for *Diacavolinia* based on geometric morphometric information, because specimens from the Gulf of Aden and entrance of the Red Sea were always assigned to multiple groups per location (18% unassigned). Because no genetic information was available, we could not infer whether the Red Sea has exported *Diacavolinia* biodiversity over time, or if it is an area of incipient speciation and local endemism due to its peripheral position and unique oceanographic conditions within a wide Indo-Pacific distribution. Fossil records have indicated that the latter is more likely for pelagic taxa because of loss of plankton diversity in the central Red Sea during low sea level stands in Pleistocene glacial maxima, and hypersaline conditions caused by almost complete isolation from the Indian Ocean (Fenton et al., 2000). Conversely, there is also evidence that some taxa increased in abundance due to freshwater dilution in the Gulf of Aqaba, such as observed in *Creseis* pteropods and siliceous diatoms (Reiss et al., 1980; Fenton et al., 2000; Almogi-Labin et al., 2008). Furthermore, some Red Sea lineages are older than their respective sister lineages in the Indian Ocean, suggesting export of biodiversity from the Red Sea, such as for some reef fishes (DiBattista et al., 2013). Peripheral speciation was observed for the spiny lobster *Panulirus penicillatus* with a 9-month larval stage, as well as for several reef fish taxa (Liu et al., 2014; Fernandez-Silva et al., 2015; Iacchei et al., 2016).

The high number of *Diacavolinia* taxa in the Indo-West Pacific (IWP) reflects the high overall marine diversity in the area (e.g., Renema et al., 2008; Becking et al., 2016). We found that the most common taxa were distributed across a broad range in the Sino-Japanese, Central Pacific, and Indian Ocean waters. There are no large-scale environmental gradients in the Indo-West Pacific that limit the distributions of *Diacavolinia* taxa, such as observed in the Red Sea, and present-day waters would appear to be deep enough to enable diel vertical migration in the epi- and

upper mesopelagic zones. However, more genetic sampling in this area is needed to further resolve species boundaries in *Diacavolinia*, clarify the high genetic and presumably cryptic diversity within Group 5, and explore IWP endemism. Also for genetic lineages of *Pleuromamma xiphias* copepods, which are deep diel migrators (>400 m), broad distributions as well as one endemic clade were found within the IWP (Goetze, 2011).

Across all oceans, we observed no obvious equatorial dispersal barriers separating the distributions of extant *Diacavolinia* taxa, but our Group 2 (no genetic information available) only occurred in the subtropical Atlantic waters north of the equator. We also found no evidence for equatorial genetic breaks within groups. Equatorial dispersal barriers may be important drivers of pelagic evolution for other taxa, such as shown for subtropical Atlantic copepods (Goetze et al., 2015, in press) and pteropods (Burridge et al., 2015: Thesis chapter 3).

CONCLUSIONS

Combining varied datasets in an integrative taxonomic approach may be suitable for a wide array of morphologically diverse marine taxa and is an essential first step to predicting species-specific ecological and evolutionary responses to ocean change. Museum collections prove to be an invaluable reference for assessing species boundaries and biogeographic distributions using modern techniques, enabling comparison of our findings with prior works based on the same specimens. We assessed species boundaries in *Diacavolinia* pteropods based on rigorous sampling over a time period of 104 years and data collection across the Atlantic, Pacific, and Indian oceans. Our results show that taxonomic revisions of *Diacavolinia* are needed, and will be reported on in subsequent work. However, still not all species boundaries are resolved and some rare species were only sampled once.

ACKNOWLEDGEMENTS

We thank A. Tsuda and R.A. Gasca Serrano for generously providing freshly collected *Diacavolinia* samples from the Atlantic and Pacific oceans, J. van Arkel for his assistance in specimen photography, and M. Eurlings, K. Beentjes, M.K. Dijkstra, O.D. Schaap, L. Dong, B. Voetdijk, and P. Kuperus for technical assistance in the molecular lab. We are grateful to A.W. Jansen for his ideas, thorough knowledge of pteropod fossils, and comments on this manuscript. Finally, we thank J. Huisman and S.B.J. Menken for their helpful comments on this manuscript. This work was supported by the Royal Netherlands Institute for Sea Research (NIOZ) for cruise participation, the Royal Netherlands Academy of Sciences Ecology Fund (KNAW Fonds Ecologie) Research grant 0205510763, and The Malacological Society of London Research grant to A.K. Burridge, a Netherlands Organisation for Scientific Research (NWO) cruise participation grant, and VENI grant 863.08.024 to K.T.C.A. Peijnenburg. E. Goetze and collections in this study were supported under National Science Foundation grants OCE-1029478, OCE-1255697 and OCE-1338959, as well as Hawaii state support for ship time on R/V Kilo Moana in 2011 (U Hawaii OCN627 student training cruise, KM1109). We also thank the Sea Education Association (S226), and D. Kobayashi and L. Giuseffi (SE1201) for assistance with collections. This is contribution number 294 of the Atlantic Meridional Transect Programme. The authors declare that they have no competing interests.

SUPPLEMENTARY INFORMATION

The data set supporting the results of this chapter is available upon request and will be deposited at the Dryad Digital Repository once this manuscript is accepted for publication in a peer-reviewed journal. DNA sequences have been deposited at GenBank under the following accession numbers: MF974624-MF974847.

SUPPLEMENTARY INFORMATION 1. Photographs of *Diacavolinia* specimens included in this study in (A) ventral and (B) lateral orientations.

SUPPLEMENTARY INFORMATION 2. Geometric morphometric data of *Diacavolinia* specimens: centroid sizes and relative warps in ventral (A: 23 and B: 38 landmarks) and lateral orientations (C: 15 and D: 49 landmarks).

FIGURE S1. Ordination of the second and third relative warps (RWs) of *Diacavolinia* for Indo-Pacific specimens for (A) lateral orientation with 49 landmarks (LMs; $N = 282$), (B) ventral orientation with 23 LMs ($N = 378$), and (C) ventral orientation of a subset with 38 LMs ($N = 174$). See FIGURE 4 for symbol definitions. Corresponding thin plate splines of the most positive and negative deformations are indicated along the axes to depict the variation in shell shape.

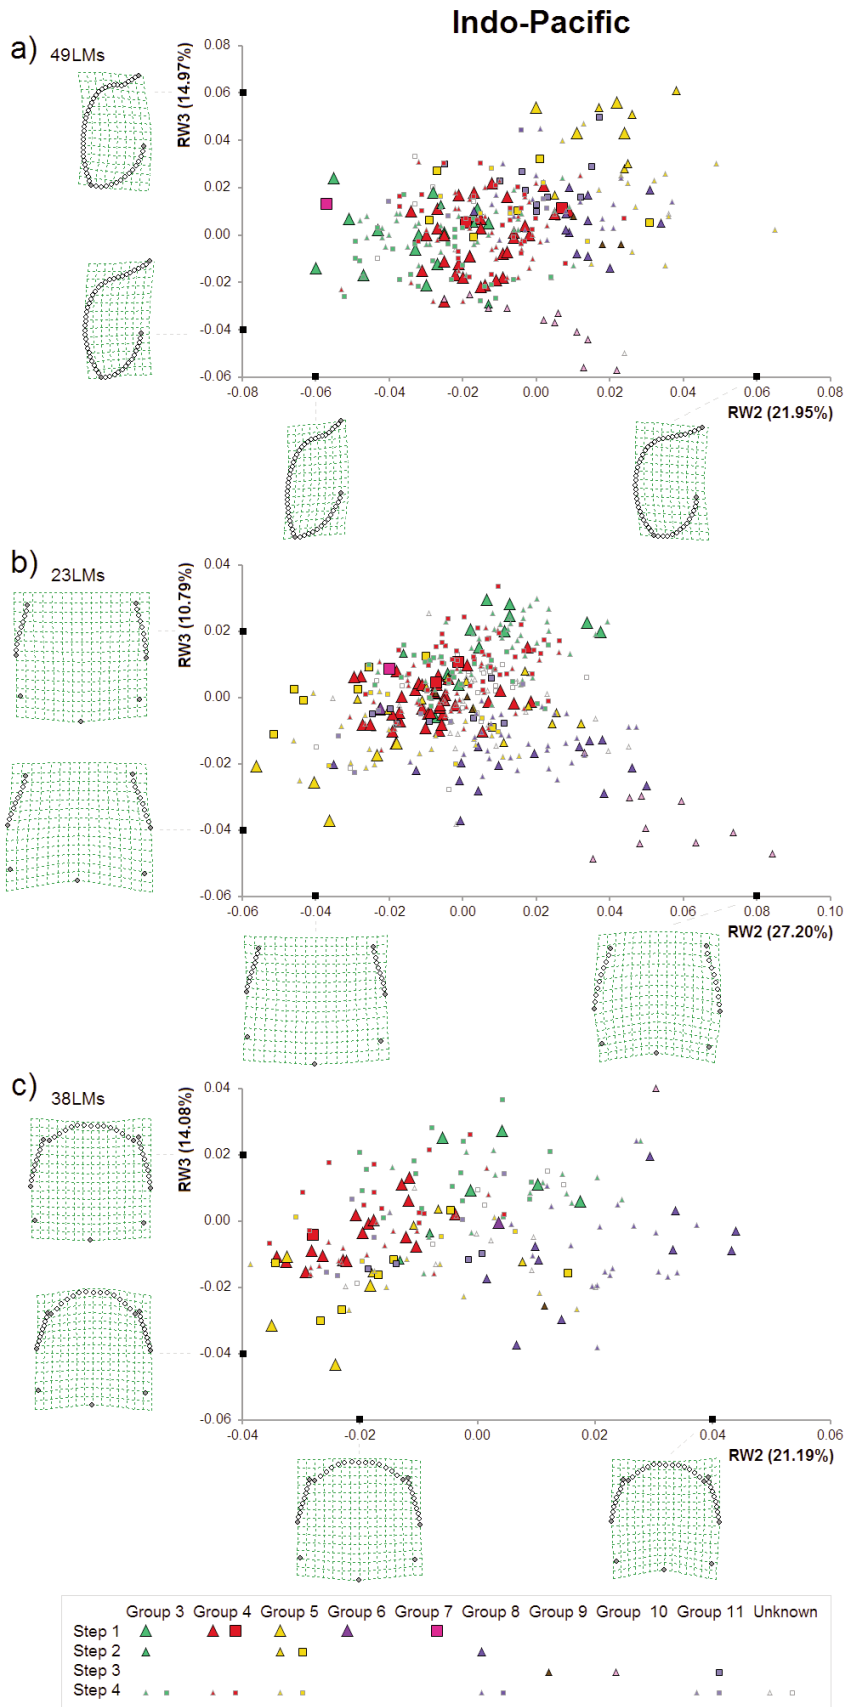

TABLE S1. Sample collection information, group assignment using integrative approach, data usage for geometric morphometric analyses, and GenBank accession codes for each *Diacavolinia* specimen used in this study. Amb. = Ambiguous LDA assignment; Unkn. = Unknown integrative group; N.A. = Not available.; *D. v.* = *Diacavolinia vanutrechtii*.

6

Diversity and abundance of pteropods and heteropods along a latitudinal gradient across the Atlantic Ocean

Alice K. Burridge, Erica Goetze, Deborah Wall-Palmer,
Serena L. Le Double, Jef Huisman & Katja T.C.A. Peijnenburg

ABSTRACT

Shelled pteropods and heteropods are two independent groups of holoplanktonic gastropods that are potentially good indicators of the effects of ocean acidification. Although insight into their ecology and biogeography is important for predicting species-specific sensitivities to ocean change, the species abundances and biogeographical distributions of pteropods and heteropods are still poorly known. Here, we examined abundance and distribution patterns of pteropods (euthecosomes, pseudothecosomes, gymnosomes) and heteropods at 31 stations along a transect from 46°N to 46°S across the open waters of the Atlantic Ocean (Atlantic Meridional Transect cruise AMT24). We collected a total of 7312 pteropod specimens belonging to at least 31 species. Pteropod abundances were low north of 40°N with <15 individuals per 1000 m³, varied between 100 and 2000 ind./1000 m³ between 30°N and 40°S, and reached >4000 ind./1000 m³ just south of 40°S. This accounted for an estimated biomass of 3.2 mg m⁻³ south of 40°S and an average of 0.49 mg m⁻³ along the entire transect. Species richness of pteropods was highest in the stratified (sub)tropical waters between 30°N and 30°S, with a maximum of 15 species per station. The biogeographical distribution of pteropod assemblages inferred by cluster analysis was largely congruent with the distribution of Longhurst's biogeochemical provinces. Some pteropod species distributions were limited to particular oceanographic provinces, for example, subtropical gyres (e.g., *Styliola subula*) or warm equatorial waters (e.g., *Creseis virgula*). Other species showed much broader distributions between ~35°N and ~35°S (e.g., *Limacina bulimoides* and *Heliconoides inflatus*). We collected 1812 heteropod specimens belonging to 18 species. Highest heteropod abundances and species richness were found between 30°N and 20°S, with up to ~700 ind./1000 m³ and a maximum of 14 species per station. Heteropods were not restricted to tropical and subtropical waters, however, as some taxa were also relatively abundant in subantarctic waters. Given the variation in distribution patterns among pteropod and heteropod species, it is likely that species will differ in their response to ocean changes.

INTRODUCTION

Shelled pteropods and heteropods are holoplanktonic gastropods with aragonite shells that are vulnerable to the effects of ocean acidification (e.g., Bednaršek and Ohman, 2015; Gattuso et al., 2015; Wall-Palmer et al., 2016a). They are common components of the marine zooplankton and have highly diverse evolutionary histories, life strategies and morphologies. Through production of aragonitic shells, they are involved in biogenic carbon export from the surface to the deep ocean (Bednaršek et al., 2012a). However, especially in the open Atlantic Ocean, their species diversity and abundance are still poorly understood (e.g., Bé and Gilmer, 1977; Van der Spoel and Heyman, 1983; Richter and Seapy, 1999; Van der Spoel and Dadon, 1999; Bednaršek et al., 2012a). The pteropod distribution maps from Bé and Gilmer (1977) and Van der Spoel and Heyman (1983) are based on manual estimations of distributions based on synthesized presence-only data, precluding any quantitative comparisons within and between ocean basins. Gaining more insight into the current diversity and distribution of planktonic gastropods is important for measuring future changes in diversity and distribution, and for predicting species-specific sensitivities to ocean changes. New data on abundance will help estimate the biomass of holoplanktonic gastropods, about which little is known for many regions, including the open Atlantic Ocean. This is important for their incorporation as a plankton functional type in ecosystem models and to estimate their contribution to ocean carbon export in biogeochemical models (Bednaršek et al., 2012a).

The oceans appear to have more biodiversity and less homogeneous species communities than has long been assumed or expected (Angel, 1993; Norris, 2000). Biogeochemical provinces of the Atlantic Ocean provide a diverse range of ecological niches as well as barriers to dispersal for zooplankton taxa (e.g., Peijnenburg and Goetze, 2013; Andrews et al., 2014; Goetze et al., in press). For example, in *Cuvierina* pteropods, *C. cancapae* is endemic to the equatorial Atlantic and *C. atlantica* is restricted to the northern and southern subtropical gyres (Janssen, 2005; BurrIDGE et al., 2015: Thesis chapter 3). Endemism of evolutionary lineages in the equatorial Atlantic is a pattern also observed in other plankton groups (e.g., Hirai et al., 2015; Goetze et al., in press). The species composition of planktonic ostracod assemblages also is more similar within ocean provinces (e.g., northern temperate, northern subtropical gyre and equatorial regions) than between provinces (Angel et al., 2007). Ocean warming and acidification may cause shifting species distributions in the plankton (e.g., Beaugrand et al., 2009; Provan et al., 2009), as well as (local) extinctions or adaptation to new conditions (e.g., Collins, 2012; Lohbeck et al., 2012, 2014).

Pteropods are a group of heterobranch gastropods (Jörger et al., 2010), a superorder comprised of the orders Thecosomata, also referred to as 'sea butterflies', and Gymnosomata, or 'sea angels' that play an important role in marine food webs (Lalli and Gilmer, 1989; Pierrot-Bults and Peijnenburg, 2015). According to the World Register of Marine Species (WoRMS), a total of 83 extant thecosome

species and 43 gymnosome species occur worldwide, and many fossil species also have been described (Janssen and Peijnenburg, 2014). Most taxa are between 0.05 and 2 cm in size and occur in the upper 300 m of the global ocean, although some species occur at bathypelagic depths (Bé and Gilmer, 1977; Van der Spoel and Dadon, 1999). Many species are known to be vertical migrators that move to shallower depths at night (Bé and Gilmer, 1977). Most thecosomes have aragonite shells, which they maintain as adults. They include the cavoliniid euthecosomes with uncoiled, bilaterally symmetrical shells (52 species), limaciniid euthecosomes with coiled shells (eight species), and pseudothecosomes, with coiled shells or a semi-soft pseudoconch without an aragonitic shell (23 species; Van der Spoel and Dadon, 1999). All thecosomes produce and deploy mucus webs to feed on microplankton (Gilmer and Harbison, 1986). Gymnosomes have larval shells, but shed them as they grow into adults. They are predators that feed exclusively or primarily on thecosomes (Lalli and Gilmer, 1989).

Heteropods or 'sea elephants', formally known as Pterotracheoidea, are a group of Caenogastropoda. According to WoRMS, this group consists of 35 extant species that occur in moderately low abundance in the global ocean, primarily at tropical and subtropical latitudes (Richter and Seapy, 1999). However, there is evidence that some taxa thrive in cold waters, e.g., south of Australia and during glacial periods in the geological past (Howard et al., 2011; Wall-Palmer et al., 2014). The vertical distribution of heteropods is not well understood, but they have been found to live at epipelagic and upper mesopelagic depths (e.g., Lalli and Gilmer, 1989; Richter and Seapy, 1999; Ossenbrügger, 2010). Heteropods are visual predators with well-developed eyes. To the extent that it is known, adults feed on other zooplankton and small fishes, and juveniles feed on phytoplankton and small zooplankton (Lalli and Gilmer, 1989; Seapy et al., 2003). The three heteropod families, Atlantidae, Carinariidae and Pterotracheidae, are highly diverse in size and body form. The Atlantidae have the highest species diversity (21 species; one additional species described by Wall-Palmer et al., 2016b), are generally less than 1 cm in size, are the least efficient swimmers of all heteropods, and can retract their bodies entirely into their keeled, dextrally coiled aragonite shells (Seapy et al., 2003). They are the most thoroughly sampled heteropod group in the southern subtropical Atlantic, with species densities of 410-1710 individuals per 1000 m³ accounting for 80-99% of the total sampled heteropod community (Richter and Seapy, 1999). The Carinariidae (9 species) have a cylindrical body that is very large in relation to their shells, and can be as long as 50 cm (Lalli and Gilmer, 1989). The Pterotracheidae (5 species) only have larval shells, and have an elongated body that can reach a length of 33 cm in the Atlantic Ocean (Richter and Seapy, 1999). The Carinariidae and Pterotracheidae are thought to be more efficient swimmers than Atlantidae because of the relatively small body size and large shell of the latter group (Lalli and Gilmer, 1989).

In this study, we quantitatively sampled pteropods and heteropods from 46°N to 46°S along a transect of >12,000 km across the Atlantic Ocean, during Atlantic

Meridional Transect (AMT) cruise 24. The AMT is a multidisciplinary programme aimed at understanding biological, chemical, and physical oceanographic processes, with annual transect sampling across the Atlantic Ocean (Rees et al., 2015). Here we (1) assess species distributions, abundances and biomass of pteropods and heteropods at 31 sampling stations along the transect, (2) estimate biogeographical trends in species diversity, and (3) compare inter-station similarities in community structure with Longhurst's (1998) biogeochemical provinces. To our knowledge, this is the first paper to report quantitative abundance data of pteropods and heteropods across a large-scale latitudinal gradient in the Atlantic.

METHODS

SAMPLING AND SORTING

Holoplanktonic gastropods were collected during the AMT24 expedition (United Kingdom to Falkland Islands) between 46°23'N and 46°05'S from September 28th to October 30th, 2014 (TABLE 1). We conducted oblique tows at night from the upper 311 (216-401) m at 31 stations, representing the epipelagic and upper mesopelagic zones. The stations were assigned to biogeochemical provinces according to Longhurst (1998) and Reygondeau et al. (2013; TABLE 1). We used a bongo net of 0.71 m diameter and 200 µm mesh size with a General Oceanics flowmeter (2030RC) mounted in the mouth of the net to measure the volume of seawater filtered during the tow. The flowmeter was calibrated both pre- and post-cruise. Bulk zooplankton samples were quantitatively split using a Folsom plankton splitter and one or more quantitative fractions were immediately preserved in 96% ethanol. The alcohol was replaced within 24 h of collection, and samples were stored at -20°C. Pteropods and heteropods were sorted from 25% or 50% of the quantitative zooplankton samples, depending on the bulk sample volume (TABLE 1).

Pteropod and heteropod material was sorted by species and counted after the expedition. The majority of taxa could be identified to species morphologically. However, we counted individuals in larval or juvenile growth stages separately if they could not be assigned to species because they lacked the morphological characters to distinguish between closely related species. This ambiguity occurred for juvenile *Cuvierina* euthecosomes (Bé et al., 1972), larval stages of *Diacria* and *Cavolinia* euthecosomes, *Peracle* pseudothechosomes, as well as larval stages of some atlantid heteropods. Some other taxa were registered only at the genus level because of their complex and unresolved taxonomies, including *Diacavolinia* euthecosomes, *Corolla* and *Gleba* pseudothechosomes, and *Pterotrachea* heteropods (Van der Spoel et al., 1993; Richter and Seapy, 1999; Van der Spoel and Dadon, 1999). Two formae of the euthecosome *Clio pyramidata*, forma *lanceolata* and forma *pyramidata*, were recorded together as *C. pyramidata* because these varieties were not found to be genetically distinct (Jennings et al., 2010), and likely represent a single species. We identified gymnosomes to order because we could not identify them to species following fixation in ethanol, and excluded them from

TABLE 1. Overview of sampling locations and tow information along AMT24 and corresponding CTD stations, surface temperatures and maximum chlorophyll *a* concentrations from the upper 300 m. The biogeochemical provinces of the sampling stations are based on Longhurst (1998) and Reygondeau et al. (2013): NADR (North Atlantic drift), NAST E (Northeast Atlantic subtropical gyre), NAST W (Northwest Atlantic subtropical gyre), NATR (North Atlantic tropical gyre), WTRA (Western tropical Atlantic), SATL (South Atlantic gyre), SSTC (Southern subtropical convergence), SANT (Subantarctic water ring), FKLD (Southwest Atlantic shelves).

many subsequent analyses. The ratio between the abundances of gymnosomes, if present, and thecosomes was calculated to estimate the potential predation intensity by gymnosomes on thecosomes across the AMT24 transect. This ratio was calculated only for stations with more than 10 pteropod specimens.

SPECIES DIVERSITY, ABUNDANCE AND BIOMASS

To summarize the diversity of thecosomes and heteropods along AMT24, we calculated species richness R , Shannon-Wiener's diversity index H' and Pielou's evenness index J' at each station. Shannon-Wiener's H' is commonly used as a measure for species diversity in a community and accounts for abundance and evenness of the species present (Shannon and Weaver, 1949; Spellerberg and Fedor, 2003):

$$H' = - \sum_{i=1}^R (p_i \ln p_i)$$

In this formula, R is the species richness or total number of species, and p_i is the fraction of individuals belonging to species i relative to the total number of specimens. Pielou's evenness J' is derived from H' and quantifies how close in numbers or abundance each species is in an environment, given that there are at least two species present per location (Pielou, 1967):

$$J' = \frac{H'}{\ln R}$$

To assess trends in species diversity and abundance of thecosomes and heteropods, we analyzed our gastropod diversity and abundance data in relation to oceanographic data obtained during AMT24. Abundances of pteropods and heteropods were quantified in terms of individuals per 1000 m³ of seawater filtered. Ocean temperature and chlorophyll a concentrations along AMT24 were obtained using a Sea-Bird Electronics 3P Temperature Sensor and a CTG Aquatracka MKIII Fluorometer. Oceanographic data were calibrated and archived by the British Oceanographic Data Centre (BODC). Sea surface temperature was measured at 10 m depth. Contour plots of temperature and chlorophyll a concentration in the upper 300 m were prepared in Ocean Data View 4 (Schlitzer, 2015). This depth range represents the zooplankton tow depth as well as the depth range of most pteropod and heteropod species. We examined whether species richness R showed a relationship with sea surface temperature and maximum chlorophyll a in the upper 300 m using regression analysis in the software package PAST 2.17 (Hammer et al., 2001).

We calculated the pteropod biomass in terms of total dry weight from the abundances and shell sizes using mostly genus-specific formulae from Bednaršek et al. (2012a). The formulae are presented in TABLE S1. These were only available for euthecosomes and gymnosomes, so we did not include shelled pseudothecosomes (*Peracle* species) and heteropods in our calculations. These formulae use estimated averages of shell length and width. Because some suggested size averages clearly overestimated the observed sizes along AMT24, we adjusted them to represent the collected speci-

mens along AMT24 (TABLE S1). We did this for *Clio cuspidata*, *C. pyramidata*, *C. pyramidata antarctica*, *C. pyramidata sulcata*, *Cuvierina* sp., *Styliola subula*, *Hyalocylis striata* and gymnosomes. Average sizes of *Clio recurva*, *Cavolinia gibbosa* and *Diacavolinia* were not indicated by Bednaršek et al. (2012a), so we used our own size estimates as well as their genus-level formulae to estimate their dry weight (using the *Cavolinia* formula for *Diacavolinia*). We used the formula for *Limacina helicina* (Bednaršek et al., 2012b) for all coiled euthecosomes. Bednaršek et al. (2012b) estimated that ~27% of the total carbon of *L. helicina antarctica* consisted of inorganic carbon.

SPECIES COMPOSITION

For subsequent analyses of inter-station similarities of species composition, sampling completeness and relative species dominance, we reduced our abundance dataset to exclude small sample sizes as follows. We excluded all stations with fewer than 10 thecosomes or heteropods, all larval and juvenile specimens that could be assigned to two or more species, and all identified species that only occurred at one selected station. The stations that were excluded from analyses of thecosome species composition were 1-4 and 31 because there were fewer than 10 specimens that could be identified to species or genus level. The thecosome species or genera that were excluded because they were observed at only one station were *Cavolinia gibbosa*, *Clio recurva*, *Diacria major*, *Gleba* and *Corolla*. *Cuvierina* juveniles and adults were binned into a single genus-level group because upon exclusion of the juveniles there would not be enough specimens (one adult: *Cuvierina atlantica*). For heteropods, we excluded stations 1-5, 12, 22, 24-26 and 30-31; also *Atlanta oligogyra* was excluded.

To examine whether the distributions of distinct species assemblages correspond with the distribution of Longhurst's (1998) biogeochemical provinces as defined by biogeochemistry and ecosystem dynamics, we quantified and visualized inter-station similarities of species composition and identified key species. For inter-station comparisons we performed a hierarchical cluster analysis, similarity profile analysis (SIMPROF), and non-metric multidimensional scaling analysis (nMDS) in PRIMER 6, without a priori assumptions (Clarke, 1993; Clarke and Warwick, 2001; Clarke and Gorley, 2006). To perform cluster analysis, SIMPROF and nMDS, we standardized and transformed ($\log [x + 1]$) the abundance data and then calculated a Bray-Curtis similarity matrix. For the cluster analysis we used the group average setting. The significance of the clusters was tested with SIMPROF analyses using 1000 permutations and a significance level of $p < 0.05$. The nMDS ordinations were performed with 25 restarts. Furthermore, we created rank abundance curves based on the thecosome species abundances at each station in order to assess patterns of dominance across ocean biomes.

To assess sampling completeness, we created sample-based as well as individual-based rarefaction curves for thecosomes and heteropods in Primer 6 (Clarke and Gorley, 2006) and PAST 2.17 (Hammer et al., 2001). The sample-based curves were based on the Jackknife 2 index (Gotelli and Colwell, 2010) and only included non-transitional stations that belong to distinct biogeochemical provinces.

RESULTS

SPECIES ABUNDANCE, BIOMASS AND DIVERSITY

We counted and identified a total of 7312 pteropods across all stations on the transect, traversing the northern temperate zone, the eastern side of the northern subtropical gyre, the equatorial upwelling zone, the southern subtropical gyre, the southern subtropical convergence and the northernmost part of the subantarctic (FIGURE 1A; TABLE 1). Among the pteropod specimens, there were 1028 uncoiled and 5980 coiled euthecosomes, 230 pseudothecosomes and 74 gymnosomes. Pteropod abundances were low (<15 ind./ 1000 m^3) north of 40°N and they were absent from station 3. Their abundance varied between 100 and 2000 ind./ 1000 m^3 between 30°N and 40°S . Abundances were highest at stations 27-29, just south of 40°S , with a maximum abundance of >4000 ind./ 1000 m^3 at station 28 (FIGURES 1B,C and 2A; TABLE S2). Coiled euthecosomes were particularly abundant in this high productivi-

FIGURE 1. (A) Overview of pteropod and heteropod sampling locations along Atlantic Meridional Transect 24. (B-E) Distribution of (B) pteropods and heteropods, (C) euthecosome, pseudothecosome and gymnosome pteropods, (D) genera of uncoiled euthecosomes and (E) species of coiled euthecosomes along Atlantic Meridional Transect 24. The size of the pie charts is scaled according to the total abundance of the examined groups (size of the maximum abundance is shown in legend for each plot). True sampling locations are indicated with a white (B) or black (C-E) line if pie sizes did not allow placement at true locations.

ty area, while pseudothecosomes were more abundant in the subtropical gyres.

Gymnosomes feed almost exclusively on thecosomes. The ratio between gymnosomes, if present, and thecosomes (euthecosomes and pseudothecosomes) ranged from 0.005 to 0.019 in (sub)tropical waters between $\sim 28^{\circ}\text{N}$ and $\sim 28^{\circ}\text{S}$ (stations 7-23; TABLE S3). Gymnosomes were always present between ~ 32 and $\sim 45^{\circ}\text{S}$ (stations 24-30), with ratios between 0.012 and 0.091, suggesting higher potential predation intensity by gymnosomes on thecosomes at these southern stations than in (sub)tropical waters.

We observed taxa with strong preferences for particular oceanographic provinces, in particular among euthecosomes and pseudothecosomes (FIGURE 1C-E). In the equatorial province and in the subantarctic, the thecosome community consisted of one or two dominant species, and especially in the equatorial region a number of additional species occurred in low abundance. The relative species abundances were more equal in the subtropical gyres (FIGURE S1; abundances per species per station are listed in TABLE S2). Uncoiled euthecosomes were found between 46°N and 43°S (FIGURE 1D). Two *Clio* taxa, *C. pyramidata sulcata* and *C. pyramidata antarctica*, were restricted to the subantarctic, but were never dominant. *Clio pyramidata pyramidata/lanceolata* was found in all other regions along the transect. Key species that were most abundant in the subtropical gyres included *Creseis clava*, *Diacria danae* and *Styliola subula*, the latter of which was entirely absent in the equatorial upwelling region. Although *Cavolinia inflexa* was present across warm water environments, this species only occurred in high abundances in the southern gyre. *Creseis virgula* was found in the equatorial region and occurred nowhere else along the transect (TABLE S2). Coiled euthecosomes were found between 35°N and 46°S (FIGURE 1E). *Heliconoides inflatus* was abundant along the entire transect and did not show a clear preference for particular provinces. However, *H. inflatus* specimens in the subantarctic region were morphologically distinct from warm water *H. inflatus* specimens. Shells of the cold water form (listed as *H. inflatus* S herein) appeared to be coarser and thicker and, in contrast to the warm water form, they had a reddish hue along the whorls and aperture. *Limacina helicina antarctica* was dominant in subantarctic waters. *Limacina bulimoides* had a strong preference for the subtropical gyres, although it was also present in low numbers in the equatorial region. *Limacina lesueurii* was present throughout the warm water regions and *L. trochiformis* was only found in the southern gyre, though never in high numbers (maximum $N = 9$ at St. 20; FIGURE 1E). Most *Peracle* pseudothecosome species demonstrated a strong preference for the subtropical gyres (FIGURE 1C), but the

FIGURE 2. Basin-scale patterns of (A) pteropod abundance (individuals/1000 m^3), (B) pteropod biomass in terms of total dry weight (mg m^{-3}), (C) pteropod species richness R , (D) sea-water temperature and (E) chlorophyll a concentrations in the upper 300 m of the water column, measured during Atlantic Meridional Transect cruise 24. Lines in (A) are interrupted in case of zero abundances. Because gymnosomes were not identified to the species level, they were not included in the calculation of species richness R in (C).

large, soft-bodied genera *Corolla* and *Gleba* were only found in cooler waters north of 40°N and south of 40°S in very low numbers (never more than $N = 2$ per station).

Areas with high chlorophyll *a* concentrations had the highest estimated pteropod biomass, except the northern temperate zone, where hardly any pteropods were captured (FIGURE 2B; TABLE S4). A total biomass of more than 3.1 mg m⁻³ in the upper ~300 m was reached in the southern subantarctic region, mainly caused by high abundances of *Limacina helicina antarctica* and *Heliconoides inflatus* S. Just south of the equator there was an estimated biomass of more than 1.9 mg m⁻³ because of high abundances of *Cavolinia inflexa* and *Clio pyramidata*. The median and average pteropod biomass across all stations along AMT24 was 0.28 mg m⁻³ and 0.49 mg m⁻³, respectively.

The species richness of thecosomes was highest in the stratified (sub)tropical waters between ~30°N and ~30°S and was consistently high (11-13 species) in the southern gyre (FIGURE 2C,D), a pattern that was also evident from the Shannon-Wiener's diversity indices H' per station (TABLE S3). Uncoiled euthecosomes generally had a higher species richness than coiled euthecosomes and pseudotheicosomes

FIGURE 3. Relationships of species richness R of thecosome pteropods (euthecosomes and pseudotheicosomes) with (A) sea surface temperature and (B) maximum chlorophyll *a* concentration in the upper 300 m of the water column. Lines are based on linear regression. Grey and black dots represent locations north and south of the equator, respectively.

(FIGURE 2C). Although most equatorial stations had slightly lower species richness than the gyre stations, the highest species richness (15 species) was observed close to the equator at station 14. Species richness showed a positive relationship with sea surface temperature ($R^2 = 0.55$; $N = 30$; $p < 0.001$; FIGURE 3A) and a negative relationship with chlorophyll *a* concentration at the deep chlorophyll maximum ($R^2 = 0.57$; $N = 30$; $p < 0.001$; FIGURE 3B). We note that sea surface temperature and chlorophyll *a* were only weakly correlated ($R^2 = 0.28$; $N = 31$; $p < 0.01$), and hence the degree of collinearity between these two explanatory variables was low. The species evenness J' was highest in the subtropical gyres, especially in the southern gyre (J' up to 0.84), when disregarding the high evenness values observed at the northern temperate stations 1, 2, and 5 because of their relatively low sample sizes. At equatorial stations 13-16 the evenness was lower (J' of 0.25-0.44) than in the gyres.

From the 1812 heteropods, a total of 1312 were atlantids, 325 were pterotracheids and 175 were carinariids. Heteropods were not found at stations 1-4 and 30-31. Highest heteropod species richness (up to 14 species) as well as abundances (maximum 704 ind./1000 m³) were found in the (sub)tropical waters between ~30°N and ~20°S (FIGURE 4). A high abundance of heteropods (>100 ind./1000 m³) was also found in the subantarctic region (TABLE S2). There were no clear patterns in species evenness along the transect except a lower evenness at stations 28-29 (J' of 0.10-0.37; TABLE S3).

SPECIES COMPOSITION

The cluster and SIMPROF analyses of thecosome species composition of the different stations along AMT24 resulted in six significant clusters ($p < 0.05$; FIGURE 5A). These

FIGURE 4. Basin-scale patterns of (A) heteropod abundance (individuals/1000 m³), and (B) heteropod species richness R . Lines in (A) are interrupted in case of zero abundances.

FIGURE 5. (A) Hierarchical cluster analysis of the stations according to their community composition of thecosome pteropods (euthecosomes and pseudothecosomes). The analysis is based on all stations with at least 10 specimens, and resulted in the indicated six significant clusters (SIMPROF $p < 0.05$). (B and C) nMDS ordination based on the community composition of thecosome pteropods, (B) using all stations with at least 10 specimens, and (C) excluding the subantarctic stations 26-30. Symbols are colored according to their geographic allocation, with upward pyramids for the northern hemisphere, downward pyramids for the southern hemisphere and diamonds for equatorial locations. The Longhurst provinces (Longhurst, 1998; Reygondeau et al., 2013) of the sampling stations are indicated in (A): NAST E (Northeast Atlantic subtropical gyral), NAST W (Northwest Atlantic subtropical gyral), NATR (North Atlantic tropical gyral), WTRA (Western tropical Atlantic), SATL (South Atlantic gyral), SSTC (South subtropical convergence), SANT (Subantarctic water ring), FKLD (Southwest Atlantic shelves).

results are further confirmed by the nMDS ordination, in which the six different clusters can be clearly recognized (FIGURE 5B,C). The species composition in the subantarctic region (St. 26-30) demonstrated almost no overlap with species compositions in other regions. The other clusters consisted of the equatorial stations (St. 11-16), the northern and southern gyres together (St. 6-9 and 18-23), the northern gyre-equatorial transition (St. 10), the southern subtropical convergence (St. 25), and the northern temperate zone and southern gyre-equatorial transition (St. 5 and 17) together. Because of the overlap between species compositions in the northern temperate and in the northern and southern gyre-equatorial transitions, the ordination of St. 5 and 17 may be an artefact of the gradual nature of the transitions between oceanographic provinces (FIGURE 5). According to the rarefaction curves of the equatorial, gyre and subantarctic stations, the major oceanographic provinces traversed during AMT24 were well-sampled for thecosomes (FIGURE S2A). Although transitions between oceanographic provinces were gradual, we were not able to thoroughly sample these areas at more than one location per transition (FIGURE S2B).

Heteropod species had a wider distribution than the subtropical gyres and equatorial regions: some of them also occurred in the subantarctic (FIGURES 1B and 4). This was the case for an exclusively subantarctic and yet undescribed *Atlanta* morphotype, listed as *Atlanta* species A herein (Wall-Palmer et al., 2016b). In particular, the taxa that produce very large adults, the carinariids and pterotracheids, had patchy distributions, with high numbers at a few stations and no or a few specimens at the adjacent stations (TABLE S2). It was therefore difficult to identify large-scale biogeographical distribution patterns among the heteropods. This patchy pattern was also reflected in rarefaction curves of heteropods, which were represented by fewer samples with at least 10 specimens compared to pteropods. Suboptimal sampling of the heteropods was demonstrated especially in the rarefaction curves representing the northern subtropical gyre and subantarctic stations (FIGURE S2C,D). We did not generate rarefaction curves for heteropods from northern and southern temperate stations because they contained too few (<6) specimens.

DISCUSSION

GENERAL OBSERVATIONS

We assessed pteropod and heteropod abundances, diversity and distributions in the Atlantic Ocean based on quantitative sampling along a basin-scale transect from 46°N to 46°S, crossing seven biogeochemical provinces. The AMT programme allowed us to combine zooplankton diversity and abundance data with ocean metadata from the same expedition, providing a rich oceanographic context to explain the observed patterns (e.g., Rees et al., 2015). Our results show that the species richness of both pteropods and heteropods was highest in the tropical and subtropical Atlantic. Pteropod abundance and biomass were highest just south of 40°S, and also reached high values near the equator (FIGURES 1 and 2; TABLES S2 and S4). Some pteropod taxa showed strong preferences for particular oceanographic

provinces, for example for warm equatorial waters (e.g., *Creseis virgula*), subtropical gyres (e.g., *Styliola subula*), or in and south of the southern subtropical convergence zone (e.g., *Limacina helicina antarctica*). Other species occurred across a broad range of provinces (e.g., *Heliconoides inflatus* and *Limacina lesueurii*; TABLE S2). Most heteropods were restricted to warm waters, but some taxa also occurred in the subantarctic region.

We found no unexpected extremes in pteropod abundance along AMT24 (FIGURE 2A) and the rarefaction curves flattened with an increasing number of samples or individuals (FIGURE S2A,B), indicating that the pteropods in this study have been representatively sampled. However, it is likely that our net aperture (0.71 m) and mesh size (200 μm) are responsible for highly variable heteropod species counts, diversities and abundances across stations, and quantitative sampling of these larger taxa requires nets with larger apertures and mesh sizes (McGowan and Fraundorf, 1966; Wells, 1973; Wall-Palmer et al., 2016a). Hence, we will focus most of our discussion on pteropods.

DISTRIBUTION AND ABUNDANCE

The biogeographical distributions of pteropod assemblages inferred by cluster analysis were largely congruent with the distribution of Longhurst's (1998) biogeochemical provinces for the period from September to November (FIGURE 5; Reygondeau et al., 2013). Our pteropod species distributions in the Atlantic Ocean also were comparable with those from the qualitative biogeographical synthesis of Bé and Gilmer (1977), however, there were some exceptions. According to Bé and Gilmer, *Limacina trochiformis* was most abundant in the equatorial province (WTRA). By contrast, we observed *L. trochiformis* only at station 14 ($N = 3$) in the equatorial province, but found much higher abundances throughout the south subtropical gyre. Exact localities upon which the distribution maps of Bé and Gilmer (1977) were based were not given, so we could not deduce if and where in the South Atlantic their samples were collected. We found a cold water variant of *Heliconoides inflatus* (*H. inflatus* S herein) in the subantarctic, but the distribution map from Bé and Gilmer (1977) most likely shows the broad equatorial and subtropical distribution of the warm water *H. inflatus* (listed as *Limacina inflata*) with a southern limit at $\sim 40^{\circ}\text{S}$. The distribution of *Creseis virgula* was limited to the equatorial Atlantic in our study, but also occurred in the subtropical gyres according to Bé and Gilmer (1977). They also listed some species that were not found in our quantitative samples: the warm water species *Cavolinia tridentata* and the cold water species *Limacina retroversa*.

Because previous quantitative abundance data in provinces traversed by AMT24 are limited, our abundance data could only be compared to a few other pteropod studies. In October, St. 30 and 31 are within a transition zone between the Subantarctic water ring (SANT) and Southwest Atlantic shelves (FKLD) provinces (Reygondeau et al., 2013). Hunt et al. (2008) synthesized pteropod abundances in the Southern Ocean from tow data (1982-2006). In the mesozooplankton samples, they found low densities of *Limacina helicina antarctica* of only a few

tens of ind./1000 m³ in October, both near the Antarctic Peninsula and south of Australia, which is comparable to the low densities of 25.3-36.5 ind./1000 m³ of *L. helicina antarctica* that we found at St. 30 and 31 (45-46°S) in October. Much higher population densities of this species were found in the mid austral summer (January-February), with 103 to 104 ind./1000 m³ at the Antarctic Peninsula and south of Australia, and even 105 ind./1000 m³ near South Georgia (Hunt et al., 2008). Bednaršek et al. (2012b) report similar seasonal dynamics from the Antarctic Peninsula to South Georgia, with higher numbers of *L. helicina antarctica* in the austral summer and autumn than in the spring. We did find high densities of *L. helicina antarctica*, exceeding 103 to 104 ind./1000 m³ in October, further up north at St. 27 and 28 (40-41°S), which may indicate that the growing season for this species started earlier at lower latitudes.

The total zooplankton abundance in the upper 200 m of the northeast Atlantic Ocean during July 1996 was characterized by Gallienne et al. (2001) by vertical hauls of 200 µm mesh size nets (aperture 0.57 m). They found low pteropod abundances of 0-75 ind./1000 m³ between 39 and 47°N, comparable to 0-24.2 ind./1000 m³ between 35 and 46°N in our study in late September/early October (St. 1-5). Gallienne et al. (2001) found higher summer abundances of 845-1730 ind./1000 m³ at 37°N, whereas in our study higher abundances were found south of 31°N in early fall, which may again reflect seasonal variation.

In the Caribbean Sea, not sampled in our study, the average species abundances in the 239 µm mesh size net (aperture 1.0 m) used by Wells (1973) near Barbados resemble our findings in equatorial St. 14. For *Creseis virgula*, Wells (1973) found 16.9 ind./1000 m³, which is highly comparable to the 18.4 ind./1000 m³ in our study. For *Heliconoides inflatus*, Wells (1973) found 257.3 ind./1000 m³ resembling the 239.8 ind./1000 m³ in our study. The major difference was the high abundance of *Creseis conica* in the Caribbean (188.2 ind./1000 m³) reported by Wells (1973; listed as *Creseis virgula conica*), whereas we found only 16.8 ind./1000 m³ at our St. 14.

PLANKTON BIOMASS IN THE GLOBAL OCEAN

Qualitatively, the pteropod biomass distribution along AMT24 showed a similar large-scale pattern as the biomass distributions of many other mesozooplankton groups, with high zooplankton biomass in arctic and subantarctic waters, elevated biomass in the equatorial regions, and lowest biomass within the gyres (Moriarty and O'Brien, 2013). Quantitatively, however, biomass data from sampling locations between 10 and 500 m deep in various parts of the Atlantic Ocean as synthesized by Bednaršek et al. (2012a) point at a higher pteropod biomass (dry weight) in the Atlantic Ocean than in the Indian and Pacific oceans. This was true for the equatorial Atlantic north of Brazil, the Mediterranean Sea, and the subantarctic near South Georgia. Our data appear to confirm this. Compared to the global median pteropod biomass of 0.058 mg m⁻³ (only non-zero global data) reported by Bednaršek et al. (2012a), we found a much higher pteropod biomass per m³ in the Atlantic Ocean (FIGURE 2B; median of 0.28 mg m⁻³).

LATITUDINAL TRENDS IN SPECIES RICHNESS

The dominant paradigm for latitudinal diversity patterns in pelagic systems is a bimodal pattern of species richness, with maxima in the gyres, slightly lower richness in the equatorial province, and a sharp decrease of diversity towards the temperate and polar zones (e.g., Hillebrand, 2004a). Our pteropod data broadly support this pattern, and with the exception of one equatorial station, diversity at most stations in the equatorial province was slightly lower than in the gyres (FIGURE 2C). Many hypotheses have been formulated for advancing the ecological, biogeographic, and evolutionary understanding of the latitudinal diversity gradient, and for explaining why the gradient in the pelagic ocean differs from a steady increase of diversity towards the equator, the most widely recognized pattern in benthic and terrestrial environments (e.g., Angel, 1997; Gaston, 2000; Willig et al., 2003; Hillebrand, 2004a,b; Brayard et al., 2005). Examples of such conceptual models are the evolutionary speed hypothesis and geometric constraints hypothesis (Willig et al., 2003).

Several pelagic groups show latitudinal trends in species richness similar to pteropods, with the highest richness in the subtropical gyres. Such a pattern was reported for hydromedusans (Macpherson, 2002), euphausiids (Angel, 1997; Tittensor et al., 2010), pelagic decapods (Angel, 1997), ostracods (Angel, 1997; Angel et al., 2007), fish (Angel, 1997), foraminifera (Rutherford et al., 1999; Tittensor et al., 2010), and tintinnid ciliates (Dolan and Pierce, 2013). Several other pelagic taxa do not show a bimodal pattern with maximum species richness in the subtropical gyres, but display a diversity peak in the equatorial region or a diversity plateau across subtropical and tropical latitudes. Examples of equatorial maxima are found for salps (Macpherson, 2002) and hyperiid amphipods (Burrige et al., in press: Thesis chapter 7), and our data indicate that heteropods also show maximum species richness in equatorial waters. A wider diversity plateau across the tropics and subtropics was found for copepods (Woodd-Walker et al., 2002; Rombouts et al., 2009), siphonophore hydrozoans and cephalopods (Macpherson, 2002). Larvacean species diversity only had a clear peak in the northern gyre (Macpherson, 2002), and chaetognaths only demonstrated a peak in the southern gyre (Macpherson, 2002) with a distinct decrease in species diversity towards cold North Atlantic waters (42-59°N; Pierrot-Bults, 2008). However, the reported species diversities in the latter two groups were lower (maxima of up to ~50 and ~40 species, respectively) than for hydromedusans or crustaceans. Species diversities registered for pteropods were also comparatively low. Accurate estimates of pteropod species diversities may require more rigorous sampling efforts and more accurate assessments of species boundaries. Our anomaly of high diversity at equatorial station 14 was largely caused by the occurrence of pteropod taxa that are generally known to appear in low abundances and that were only sporadically collected along AMT24, e.g., *Diacavolinia* sp. and *Hyalocylis striata*. Repeated transect studies may compensate for such anomalies. Overall, the latitudinal diversity gradient varies among zooplankton groups, and appears to result from a complex interplay among ecological factors, highly diverse life history strategies and roles in the marine food web, as well as different evolutionary histories.

CONCLUSIONS

To our knowledge, this is the most comprehensive study of the diversity and abundance of planktonic gastropods across the Atlantic Ocean to date. We found close correspondence between our pteropod assemblages and Longhurst's (1998) biogeochemical provinces. On average, our results point to a substantially higher pteropod biomass in the Atlantic Ocean than in the Indian and Pacific oceans. The dominant paradigm of a bimodal pattern of species richness in pelagic systems, with maxima in the subtropical gyres, was broadly supported by our pteropod data. Our study provides only a snapshot in time, however. Thorough repeated sampling will be essential for examining large-scale, long-term trends in the diversity and abundance of planktonic gastropods, quantifying future changes, and predicting species-specific sensitivities to ocean changes.

ACKNOWLEDGEMENTS

We thank A.W. Janssen for his insights in taxonomy and comments on the manuscript, and M. Jungbluth, S. Cregeen and the AMT24 crew for their assistance at sea. We are grateful to M. Cusson for his advice on statistical analyses of species communities. A.K. Burridge was supported by funding through the KNAW (Royal Dutch Academy of Science) Ecology Fund UPS/297/Eco/1403J, the Netherlands Organisation for Scientific Research (NWO cruise participation grant, coordinated by the Royal Netherlands Institute for Sea Research [NIOZ]), and the Malacological Society of London Research Grant. E. Goetze and the fieldwork component of this study were supported by National Science Foundation (USA) grants OCE-1338959 and OCE-1255697. D. Wall-Palmer was funded by the Leverhulme Trust RPG-2013-363 (2014-2017) and a Martin-Fellowship from Naturalis Biodiversity Center (2015). Plankton collections made for this study were partially supported by the UK Natural Environment Research Council National Capability funding to Plymouth Marine Laboratory and the National Oceanography Centre, Southampton. This is contribution number 301 of the AMT programme.

SUPPLEMENTARY INFORMATION

FIGURE S1. Rank abundance curves describing the distribution of thecosome species abundances for each station with at least 2 species and 10 specimens. Lines are colored according to the geographical location of the stations.

FIGURE S2. Sample-based (A and C) and individual-based (B and D) rarefaction curves for (A and B) thecosomes and (C and D) heteropods, based on all stations with at least 10 specimens. (B) and (D) show the first 300 and 200 individuals, respectively. Transitional stations 5, 10, 17 and 25 are not included in the sample-based rarefaction in (A and C). Lines are colored according to the geographical location of the stations.

TABLE S1. Formulae used to calculate the biomass of euthecosomes and gymnosomes by dry weight, as adjusted from Bednaršek et al. (2012a). L = shell length [mm], D = shell diameter [mm].

Species	Formula for dry weight [mg/ind.]	L or D [mm]	Remarks if different from Bednaršek et al. (2012)
<i>Cavolinia inflexa</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	7	
<i>Cavolinia uncinata</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	6.5	
<i>Cavolinia gibbosa</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	6.5	<i>C. uncinata</i> size used; <i>C. gibbosa</i> was not indicated
<i>Cavolinia</i> sp juv	$0.28 \cdot 0.2152 \cdot L^{2.293}$	6.2	
<i>Diacavolinia</i> sp	$0.28 \cdot 0.2152 \cdot L^{2.293}$	4	<i>Cavolinia</i> formula and <i>C. longirostris</i> f. <i>strangulata</i> size used
<i>Clio cuspidata</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	No fully grown specimens: mean L adjusted from 20 to 8 mm
<i>Clio pyramidata</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	Mean L adjusted from 20 to 8 mm
<i>Clio pyramidata</i> <i>pyramidata</i> / <i>lanceolata</i>			
<i>Clio pyramidata</i> <i>sulcata</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	Mean L adjusted from 17 to 8 mm
<i>Clio pyramidata</i> <i>antarctica</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	No fully grown specimens: mean L adjusted from 17 to 8 mm
<i>Clio recurva</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	<i>Clio</i> formula used; <i>Clio recurva</i> was not indicated as a separate genus
<i>Creseis clava</i>	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	6	
<i>Creseis conica</i>	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	7	
<i>Creseis virgula</i>	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	6	
<i>Cuvierina</i> sp	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	6	Mostly juveniles: mean L adjusted from 10 to 6 mm
<i>Diacria danae</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	1.7	
<i>Diacria trispinosa</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	8	
<i>Diacria major</i>	$0.28 \cdot 0.2152 \cdot L^{2.293}$	10.7	
<i>Diacria</i> sp juv	$0.28 \cdot 0.2152 \cdot L^{2.293}$	5.9	<i>Diacria</i> spp. formula used
<i>Hyalocylis striata</i>	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	3	Mean L adjusted from 8 to 3 mm
<i>Styliola subula</i>	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	7	Mean L adjusted from 13 to 7 mm
Cavoliniidae sp	$0.28 \cdot \pi \cdot L^{(3 \cdot 3/25)}$	4	
<i>Heliconoides inflatus</i>	$0.137 \cdot D^{1.5005}$	1	<i>Limacina helicina</i> formula used; mean D adjusted from 1.3 to 1 mm
<i>Heliconoides inflatus</i> S	$0.137 \cdot D^{1.5005}$	1.5	<i>Limacina helicina</i> formula used; mean D adjusted from 1.3 to 1.5 mm
<i>Limacina bulimoides</i>	$0.137 \cdot D^{1.5005}$	3	<i>Limacina helicina</i> formula used; mean D adjusted from 2 to 3 mm
<i>Limacina helicina</i>	$0.137 \cdot D^{1.5005}$	3	Mean D adjusted from 5 to 3 mm
<i>Limacina antarctica</i>			
<i>Limacina lesueurii</i>	$0.137 \cdot D^{1.5005}$	2	<i>Limacina helicina</i> formula used; mean D adjusted from 0.8 to 2 mm
<i>Limacina trochiformis</i>	$0.137 \cdot D^{1.5005}$	1.5	<i>Limacina helicina</i> formula used; mean D adjusted from 0.8 to 1.5 mm
Gymnosomata sp	$10^{(2.533 \cdot \log(L) - 3.89095)} \cdot 1000$	3	Mean L adjusted from 12 to 3 mm

Diversity and abundance of pteropods and heteropods

TABLE S2. Abundance data for pteropods and heteropods at each station during the AMT24 cruise. Units for abundance are individuals per 1000 m³ of seawater filtered. Uncoiled euthecosomes are cavoliniids, coiled euthecosomes are limaciniids. *Clio pyramidata pyramidata/lanceolata* is labeled as *Clio pyr. pyr./lanceolata*. Numbers listed in bold report totals for that taxon. Results for heteropods (Pterotracheoidea) are also summed within each family.

Station	1	2	3	4	5	6	7	8	9	10	11	12	13
Total pteropod abundance	6	14	0	1	24	292	472	466	414	1022	410	79	441

TABLE S3. Species richness R , Shannon-Wiener's diversity index H' , Pielou's evenness index J' and the predator-prey ratio between the abundances of gymnosomes and thecosomes (euthecosomes and pseudothecones), calculated for all stations on the AMT24 cruise. Pteropod diversity indices include both euthecosomes and pseudothecones, but not gymnosomes. Zeros for H' are reported in grey because they are based on single specimens.

Diversity and distribution of hyperiid amphipods along a latitudinal transect in the Atlantic Ocean

Alice K. Burridge, Marloes Tump, Ronald Vonk,
Erica Goetze & Katja T.C.A. Peijnenburg

ABSTRACT

As commensals and parasitoids of gelatinous plankton, hyperiid amphipods play unique and important ecological roles in pelagic food webs. Because the diversity and biogeography of this group in oceanic waters is poorly known, we examined diversity and distribution patterns of hyperiids along a basin-scale meridional transect in the Atlantic Ocean (Atlantic Meridional Transect cruise 22). Hyperiids were collected from epipelagic and upper mesopelagic depths at 27 stations between 39°N and 45°S. A total of 70 species in 36 genera and 17 families were identified, the majority of which belonged to the epipelagic Physocephalata infraorder. We observed maximum species and genus richness in the equatorial upwelling region (up to 35 species, 27 genera per station; 7°N to 8°S), which appeared largely driven by increased diversity in the superfamily Platysceloidea, as well as a significant and positive relationship between species richness and sea surface temperature. Cluster analyses of hyperiid species assemblages along the transect broadly supported a division into gyral, equatorial, transitional, and subantarctic assemblages, congruent with Longhurst's biogeochemical provinces. Steepest transitions in hyperiid species composition occurred at the southern subtropical convergence zone (34-38°S). The majority of zooplankton groups show maximal diversity in subtropical waters, and our observations of equatorial maxima in species and genus richness for hyperiids suggest that the mechanisms controlling diversity in this group are distinct from other zooplanktonic taxa. These patterns may be driven by the distribution and diversity of gelatinous hosts for hyperiids, which remain poorly characterized at ocean basin scales. The data reported here provide new distributional records for epipelagic and upper mesopelagic hyperiids across six major oceanic provinces in the Atlantic Ocean.

INTRODUCTION

The amphipod suborder Hyperiidea is an exclusively pelagic marine group, distributed from the sea surface to abyssopelagic depths worldwide. With 292 species currently described and accepted in the World Register of Marine Species (WoRMS), this peracarid crustacean group is a diverse component of the marine zooplankton. The majority of hyperiid species are commensals and parasitoids of gelatinous zooplankton (e.g., Harbison et al., 1977; Madin and Harbison, 1977; Laval, 1980), with tunicates, medusae, ctenophores, and siphonophores serving as primary hosts and additional associations reported for heteropod and pteropod molluscs and radiolarians (e.g., Harbison et al., 1977; Phleger et al., 1999; Gasca and Haddock, 2004). Characterization of host-parasite relationships is an active area of research (e.g., Gasca et al., 2015; Riascos et al., 2015), and some hyperiid genera and families appear to be restricted to particular host groups while others are less selective (e.g., Harbison et al., 1977; Madin and Harbison, 1977; Laval, 1980; Lavaniegos and Ohman, 1999). The association of the hyperiid with its host may encompass the entire life history or may be restricted to particular life stages of the amphipod. A small number of hyperiid amphipods, primarily in polar environments, are free-living, and they are often biomass dominants and important prey for seabirds (Bocher et al., 2001; Waluda et al., 2010), squids (Laptikhovsky, 2002), and fishes (Shreeve et al., 2009) in these ecosystems. Predatory fishes in other ecosystems also prey on commensal hyperiids, and they can make up a large fraction of their diets (Suntsov and Brodeur, 2008; Riascos et al., 2012; Choy et al., 2013). Hyperiids are routinely sampled in net-based oceanographic sampling programs, but their gelatinous hosts are largely destroyed by conventional sampling and preservation methods. As a result, Remotely Operated Vehicle (ROV) and scuba-based live observations of host-parasite associations derive largely from coastal areas (e.g., Monterey Bay, Gulf of California, Mediterranean Sea), while hyperiid diversity and distributions are known from a broader range of ocean ecosystems (e.g., Vinogradov et al., 1996; Zeidler and De Broyer, 2009).

Hyperiids are classified into two infraorders, the primarily bathypelagic and mesopelagic Physosomata and the epipelagic and mesopelagic Physocephalata (Vinogradov et al., 1996). The majority of hyperiid diversity is contained within the Physocephalata, with approximately 65% of extant species within the 20 families of this infraorder. Particularly diverse hyperiid families include the Scinidae (Physosomata; 45 species) and the Hyperiidae (Physocephalata; 29 species, WoRMS, 2016). Early workers recognized that many morphological features of hyperiids, such as mouthpart deformation (Dittrich, 1988), are correlated with their parasitoid association with gelatinous hosts, and may result from convergent evolution, with the suborder Hyperiidea then viewed as probably polyphyletic in origin (Pirlot, 1932; Vinogradov et al., 1996). Other morphological features, such as hypertrophied olfactory and visual systems, duplications of the eyes and an array of modifications to the appendages also likely derive from their pelagic life style (Harbison et al., 1977; Laval, 1980; Hurt et al., 2013; Baldwin Fergus et al., 2015).

Recent molecular phylogenetic studies of the Hyperiidea have supported monophyly of the infraorders as well as reciprocal monophyly of superfamilies Platysce-loidea, Vibilioidea, and Phronimoidea within the Physocephalata, but also suggested novel placements for some groups (e.g., Paraphronimidae and Cystisomatidae; Browne et al., 2007; Hurt et al., 2013).

Our knowledge of the biogeography of hyperiids is limited, and most prior studies that report on the diversity of hyperiid assemblages in the Atlantic Ocean focus on particular ocean regions, often reporting species lists (e.g., Gasca, 2003, 2004, 2007). Characterizations of basin-scale patterns in the diversity and distribution of this group are rare (but see Tarling et al., 1995, southwest temperate Atlantic). Given the host-parasitoid relationship present for most hyperiid species, the large-scale patterns of hyperiid abundance and distribution are likely driven by gelatinous host abundance and diversity, as has been documented at the mesoscale in other ocean regions (e.g., Lavaniegos and Ohman, 1999; Lavaniegos and Hereu, 2009; Valencia et al., 2013). In other zooplankton groups, latitudinal diversity gradients often include subtropical maxima in diversity (species richness), with slightly lower diversity at equatorial latitudes, and dramatic declines poleward of the subtropical convergence zone (e.g., Reid et al., 1978; McGowan and Walker, 1993; Boltovskoy, 1998; Rutherford et al., 1999; Rombouts et al., 2009). A broad warm water plateau of species richness, across both subtropical and tropical waters, is another common latitudinal pattern observed in pelagic groups (e.g., Macpherson, 2002; BurrIDGE et al., in press: Thesis chapter 6). Characterizing these broad-scale diversity gradients for different pelagic groups is important if we are to better understand the drivers of and controls on pelagic diversity (Macpherson, 2002; Beaugrand et al., 2013).

In this study, we report on the diversity and distribution of hyperiid amphipods across a continuous meridional transect in the Atlantic Ocean (39°N to 45°S) in order to assess large-scale biogeographic patterns and latitudinal diversity gradients for this group. The multidisciplinary Atlantic Meridional Transect programme (www.amt-uk.org, e.g., Rees et al., 2015) provided an ideal platform to sample hyperiid amphipods across a range of open ocean ecosystems (>12,000 km transect), and to examine distribution patterns within a rich oceanographic context. Our goals were to: (1) characterize the hyperiid species occurring in the epipelagic and upper mesopelagic zone across boreal to equatorial ocean provinces in the Atlantic Ocean, (2) test for the co-occurrence of species and identify recurring hyperiid assemblages within Atlantic ocean provinces, and (3) examine whether significant changes in species composition (biogeographical boundaries) are congruent with oceanographic gradients (temperature, salinity, chlorophyll *a*) and/or Longhurst's (1998) biogeochemical ocean provinces.

METHODS

SAMPLING AND IDENTIFICATION

Bulk plankton samples were collected at 27 stations along Atlantic Meridional Transect Cruise 22 (AMT22) between October 16 and November 19, 2012 (FIGURE 1A; TABLE 1). Oblique tows were conducted with paired bongo (200 μm , 333 μm mesh) and Rectangular Midwater Trawl (RMT1, 333 μm mesh) plankton nets in the epipelagic and upper mesopelagic zone during night time at all stations except St. 42. Bongo tows were conducted on average between 319 m and the sea surface (range 150-488 m), while RMT tows were conducted over a shallower depth range (average maximum depth 152 m, range 62-216 m; TABLE 1). A LAT tag 1100 time-depth-recorder (LOTEK Wireless) was attached to the net frame to record the maximum depth of the tow. Tow durations averaged 50 min (range 38-90 min). Bulk samples were well-mixed and preserved in multiple jars. All hyperiid material examined in this study derived from the 333 μm nets (Bongo and RMT1) and was fixed in ethyl alcohol. Depending on the size of the total plankton sample, approximate fractions were examined for hyperiids, ranging from the entire original sample in oligotrophic waters, to 1 / 10 of the sample in very high biomass and low diversity regions (e.g., stations 64-74; see TABLE 1). Our approach was non-quantitative, and we therefore have focused our analyses primarily on species presence-absence, as well as on large-scale trends in diversity and species distributions. All hyperiids were counted and removed from the examined sample fraction. Hyperiids were identified based on the taxonomic keys of Bowman (1973), Bowman and Gruner (1973), Shih (1991), Vinogradov et al. (1996), and Zeidler (1999, 2003a,b, 2004a,b, 2006, 2009, 2012a,b, 2015). Representatives of all species were imaged using a Zeiss automated stacking light microscope. Voucher specimens were deposited in the Crustacea collection of Naturalis Biodiversity Center, Leiden, The Netherlands.

Conductivity-temperature-depth (CTD) casts in the upper 500 m of the water column were conducted at similar locations as the plankton tows. All plankton stations were matched to CTD casts based on geographic proximity. Seawater temperature and chlorophyll *a* concentration data were obtained using a Sea-Bird Electronics 3P Temperature Sensor and Chelsea MKIII Aquatracka Fluorometer, with data calibrated and archived by the British Oceanographic Data Centre (BODC).

DIVERSITY AND SPECIES ASSEMBLAGES

The species richness *R* and genus richness *D* for each station were used to summarize the diversity of hyperiid amphipods along the transect. We excluded juveniles of *Scina* sp. from the calculation of species richness because these specimens could not be confidently assigned. *Lycaeidae* sp. 1 was excluded from the calculation of genus diversity because this undescribed species shared morphological features of *Lycaea* as well as *Simorhynchotus* (TABLE S1). To gain insight into the underlying causes of the latitudinal trends in species richness, we tested for relationships between species diversity and environmental data by linear regression with species richness *R* as the dependent variable and sea surface temperature, chlorophyll *a*

TABLE 1. Collection information for all samples included in this study from Atlantic Meridional Transect 22. Samples indicated with an asterisk (*) by the Sample ID had sample sizes smaller than 30 specimens and were not included in statistical analyses. Oceanic provinces by Longhurst (1998) are given as NAST E (Northeast Atlantic subtropical gyral), NAST W (Northwest Atlantic subtropical gyral), NATR (North Atlantic tropical gyral), WTRA (Western tropical Atlantic), SATL (South Atlantic gyral), SSTC (South subtropical convergence), SANT (Subantarctic water ring), FKLD (Southwest Atlantic shelves).

FIGURE 1. Overview of hyperiid diversity observed in open waters of the Atlantic Ocean. (A) Distribution of hyperiid families along Atlantic Meridional Transect 22. Piecharts indicate relative abundances of families at each station >30 specimens. (B) Most commonly found representatives of the 18 families that were sampled along Atlantic Meridional Transect cruise 22. Legend colors are arranged by infraorder and superfamily of hyperiids (following the current taxonomy as presented in the World Register of Marine Species: <http://www.marinespecies.org>). All scale bars represent 1 mm.

concentration at the deep chlorophyll maximum (DCM), or the integrated chlorophyll *a* concentration in the upper 300 m of the water column as independent variables using PAST 2.17 (Hammer et al., 2001). The sea surface temperature was represented by values sampled at 10 m depth in order to minimize missing data.

Comparisons of hyperiid assemblages across stations were conducted primarily with presence-absence based measures. We completed a second analysis incorporating species relative abundance, but only including stations for which the entire sample was examined (St. 29, 35, 39, 42, 43, 47, 53, 55, 60, 62). For all analyses, we reduced our dataset to exclude stations with small sample size (<30 specimens, stations 9 and 11). We also excluded the infraorder Physosomata because these species occur primarily at bathypelagic and mesopelagic depths (Vinogradov et al., 1996), and thus were inconsistently sampled in this study. We quantified inter-station similarities by means of hierarchical cluster analysis, similarity profile analysis (SIMPROF), and non-metric multidimensional scaling analysis (nMDS) in PRIMER 6 (Clarke, 1993; Clarke and Warwick, 2001; Clarke and Gorley, 2006). First, we used a Bray-Curtis similarity matrix derived from species presence-absence data including stations 13-74 and also, separately, for warm water stations 13-64. For the second analysis incorporating relative abundance, we used a Bray-Curtis similarity matrix based on standardized and transformed ($\log [x + 1]$) species counts. The hierarchical cluster analyses were performed using the group average setting. We performed SIMPROF analyses to test the significance of the clusters using 1000 permutations and a significance level of $p < 0.05$. The nMDS ordinations were performed with 25 restarts. We inferred rank abundance curves in order to identify patterns of species dominance across ocean provinces and reported the most common species at each site.

RESULTS

DIVERSITY

A total of 3645 hyperiid specimens were counted and identified to 70 species belonging to 17 families (FIGURE 1A; TABLE S1). The most common species found along the AMT22 transect for each family are shown in FIGURE 1B. Sixty-six of the species sampled belonged to the Physocephalata infraorder ($N = 3509$ specimens), while four species belonged to the Physosomata ($N = 136$, including *Scina* specimens not identified to species). In our samples, Physocephalata were represented by four of the five described superfamilies, 15 of the 20 described families and 34 of the 56 described genera. Of the four Physocephalata superfamilies sampled, Platysceloidea was the most diverse (six families, 17 genera, 33 species), followed by Phronimoidea (six families, 14 genera, 25 species). The least diverse superfamilies were Vibilioidea (two families, two genera, seven species) and Lycaeopsoidea (one family, one genus, one species). The most abundant and diverse Physocephalata family was Lestrigonidae ($N = 903$; eight species). The Physosomata infraorder was represented by two superfamilies, each represented by a single family (Lanceolidae, Scinidae) and genus (TABLES 2 and S1).

Hyperiid diversity was high in warm waters, with species richness R ranging from 15 to 36 species and genus diversity D from 13 to 27 genera at stations between 34°N and 36°S (FIGURE 2). Diversity peaked at stations located just north of the equator (4-15°N, St. 29, 31, 35, 37) with 29-36 species present in this region. In cooler waters south of 38°S (St. 66-74), hyperiid diversity declined to between three and nine species (FIGURE 2A; TABLE S1). A peak in species diversity associated with the equatorial upwelling region is apparent for Platysceloidea

FIGURE 2. Basin-scale patterns of (A) total hyperiid species richness R and genus richness D , (B) species richness R of superfamilies *Vibilioidea*, *Phronimoidea* and *Platysceloidea* (Physocephalata), and (C,D) seawater temperature and chlorophyll a concentrations in the upper 300 m of the water column along AMT22. Vertical lines in (C) and (D) mark the sampling locations for this study.

TABLE 2. Overview of relative abundances of hyperiid species across six Longhurst ocean provinces sampled on Atlantic Meridional Transect cruise22 (AMT22). Species are listed by superfamily and family. Relative abundances report the percentage (%) of total specimens averaged within each oceanographic region. The first column per oceanographic region lists how common species are within that region: rare (R: <5.0% of total specimens averaged within that region); common (C: 5.0 – <15.0%); or abundant (A: = or >15.0%). The number of stations in which the species was found in each province is noted within brackets.

(Physocephalata), the most diverse superfamily in our data, with a maximum of 18 species present at station 35 (FIGURE 2B; TABLE S1). Phronimoidea (Physocephalata), the second most diverse superfamily in our study, showed a different pattern with highest species diversity observed between 29°N and 11°S at stations 17-47 (11-15 species). Species richness for this superfamily was between seven and 11 species in the central and southern parts of the southern gyre between 18 and 36°S at stations 51-64 (FIGURE 2B; TABLE S1). We found a significant and positive relationship between hyperiid species richness and sea surface temperature ($R^2 = 0.65$; $N = 27$; $p < 0.001$; FIGURE 3). However, there was no significant relationship between species richness and maximum chlorophyll *a* concentration ($R^2 = 0.02$; $N = 27$; $p > 0.05$) or between species richness and integrated chlorophyll *a* in the upper 300 m ($R^2 = 0.14$; $N = 27$; $p > 0.05$).

We found two species that have previously been reported to occur only in the Pacific and Indian oceans: *Scina curilensis* and *Tullbergella cuspidata* (TABLE S1). We

FIGURE 3. Relationship between hyperiid species richness R and sea surface temperature. Linear regression and R^2 value as reported in the legend.

also found six morphologically distinct hyperiids that may represent undescribed species, and are treated as species herein. These were listed as *Lanceola* sp. 1, *Lestrigonus* sp. 1, *Brachyscelus* sp. 1, *Lycaea* sp. 1 and 2, and Lycaeidae sp. 1.

DISTRIBUTION PATTERNS

Some of the well-sampled hyperiid families were present in both warm and cold waters along the AMT22 transect (Phrosinidae, Platyscelidae, Scinidae, Vibiliidae), while other families were restricted to warmer waters, occurring only as far south as 34°S (St. 62; Brachyscelidae, Lycaeidae, Oxycephalidae), 36°S (St. 64; Lycaeopsidae, Paraphronimidae, Pronoidae) or 38°S (St. 66; Lestrogonidae, Phronimidae). The Hyperiidae showed a different pattern: they were found sporadically in warm waters, but dominated in the subantarctic (St. 66-74; FIGURE 1A; TABLES 2 and S1). Species distribution patterns were highly diverse (TABLE S1). Many hyperiid species were present across a broad warm water range, including *Eupronoe maculata*, *Hyperietta stephensi*, *Lycaeopsis themistoides*, *Phronimella elongata*, *Phronimopsis spinifera* and *Primno latreillei*. Some species were restricted to locations in or near the equatorial region (e.g., *Vibilia borealis*) or the subtropical gyres (*Eupronoe minuta*). Other species were found only in the northern gyre and sometimes also in the (near-)equatorial region, but were absent from or very rare in the southern gyre (e.g., *Amphithyrus bispinosus*, *Hyperietta vosseleri*, *Parapronoe campbelli*, *Phronima stebbingi*, and *Primno johnsoni*). *Themisto gaudichaudii* and *Vibilia stebbingi* were found at southern transitional and subantarctic locations. Several species occurred across a wide range of warm and cold water regions along AMT22, sometimes with intermittent or disjunct distribution patterns. For example, *Vibilia armata* was absent in the central part of the southern gyre and *Primno evansi* was absent in the equatorial region. Such wide distribution patterns are questionable, and it is possible that some of these species represent a complex of morphologically similar, or cryptic, species.

SPECIES ASSEMBLAGES

Hyperiid species composition differed significantly between stations along AMT22. The cluster and SIMPROF analyses based on species presence-absence identified three clusters ($p < 0.05$; FIGURE 4A), which are also apparent in the nMDS ordinations (FIGURE 4B,C). The species composition of subantarctic stations in the first cluster (St. 66, 68, 70, 72 and 74; 38-46°S) was most distinct from all other regions (15% similarity). A second cluster represented all stations from 13 to 64 except St. 62 (34°S), which was significantly distinct from all other stations in this analysis. The ordination of St. 64 may be artifactual, caused by the relatively small sample fraction that was examined at this station (TABLE 1). Stations 62 and 64 are located in southern temperate waters and represent transitional species assemblages between the southern subtropical gyre and subantarctic provinces. The equatorial stations 35, 37, 39, 42, 43 and 45 (7°N to 8°S) grouped together, although this cluster was not statistically significant (FIGURE 4). In analyses that included relative species abundance data and only included stations that were examined in their

entirety (11 stations, excluding the subantarctic region), we obtained three significant clusters ($p < 0.05$; FIGURE 5A). One cluster represented the equatorial upwelling region (St. 35, 39, 42, 43), another consisted of the northern and southern gyre stations combined (St. 29, 47, 51, 53, 55, 60), and the southern temperate St. 62 was distinct. These results were congruent with analyses based on presence-absence data only, but these analyses were better able to resolve the equatorial upwelling region as a distinct cluster (FIGURE 5).

FIGURE 4. Species assemblages of Atlantic Physocephalata hyperiids based on presence-absence data for stations with >30 specimens. (A) Hierarchical cluster analysis of stations, according to their species composition. Three significant clusters are shown (SIMPROF $p < 0.05$). (B,C) Non-metric Multi-Dimensional Scaling (nMDS) ordination based on the species assemblage of hyperiids (B) using all stations, and (C) excluding the subantarctic stations 66, 68, 70, 72 and 74. Symbols are colored according to Longhurst provinces, with upward triangles for the northern hemisphere, downward triangles for the southern hemisphere and diamonds for equatorial locations.

The geographic distribution of hyperiid species assemblages corresponded to Longhurst’s biogeochemical provinces (Longhurst, 1998), with seasonal positions as estimated by Reygondeau et al. (2013). Our analyses separated between the equatorial (western tropical Atlantic, WTRA), gyral (northwest Atlantic subtropical gyral, NAST W; north Atlantic tropical gyral, NATR; south Atlantic gyral, SATL), subantarctic (south subtropical convergence, SSTC; subantarctic water ring – southwest Atlantic shelves, SANT-FKLD), and temperate, transitional (SATL-SSTC) stations (FIGURES 4 and 5; TABLE 1). Stations from the NAST W province had similar species assemblages, although not significantly different from other gyre stations (FIGURE 4; TABLE 1).

FIGURE 5. Species assemblages of Atlantic Physocephalata hyperiids based on relative abundance data for stations that were examined in their entirety (>30 specimens). (A) Hierarchical cluster analysis of stations, according to Physocephalata species composition and relative abundance (see TABLE 1). Three significant clusters are shown (SIMPROF $p < 0.05$). (B) nMDS ordination based on the species assemblage of hyperiids. Symbols are colored as in FIGURE 4.

An overview of species composition and relative abundance of hyperiids in six regions along the meridional transect is presented in TABLE 2. In the NAST W province (St. 13, 17), *Eupronoe minuta* (17.9%) and *Lestrignus* sp. 1 (16.2%) were the most abundant species. *Primno latreillei* (10.7%), *Hyperietta stephensi* (7.3%) and *Hyperioides longipes* (6.8%) were common in the NATR province (St. 27-31). In the equatorial WTRA province (St. 35-43), the most common species were *Phronimella elongata* (13.3%) and *Hyperietta stephensi* (12.1%). In the southern gyre (SATL, St. 47-60), *Hyperioides longipes* (21.7%) and *Hyperietta stephensi* (12.3%) were the most common species. The two samples from the southern transition zone (St. 62 and 64, SATL-SSTC) demonstrated a steep transition from species common in the southern gyre toward the subantarctic hyperiid assemblage. Across these stations combined, the most common species were *Primno evansi* (18.3%), *Primno latreillei* (14.9%) and *Vibilia stebbingi* (13.4%). In the subantarctic (SSTC, SANT-FKLD, St. 66-74), *Themisto gaudichaudii* was overwhelmingly dominant (76.9%), followed by *Primno evansi* (17.9%). The rank abundance curves confirmed a pattern of strong species dominance in the subantarctic, while there was never a dominant species (>50% per station) in the warm water regions, including southern transitional stations 62 and 64 (FIGURE S1).

DISCUSSION

Hyperiid amphipods are an enigmatic macrozooplankton group and an important component of pelagic food webs. Despite their abundance in open ocean ecosystems from polar to tropical waters, hyperiid diversity and distribution patterns have not been characterized at basin-wide spatial scales. In this study, we examined the diversity and distribution of epipelagic and upper mesopelagic hyperiids along a meridional transect in the Atlantic Ocean spanning >80 degrees of latitude (39°N to 45°S). The majority of species sampled belonged to the Physocephalata infra-order, characterized by their large heads and eyes relative to their body length (FIGURE 1B). Across this transect, we identified 70 species from 17 families, of which six species represent putative undescribed species. We report new distributional records in the Atlantic Ocean for *Scina curilensis* and *Tullbergella cuspidata*, which were previously only reported from the Indo-Pacific.

LATITUDINAL DIVERSITY GRADIENTS

Overall, the dominant pattern in the latitudinal diversity gradient for hyperiids is a species diversity peak in the equatorial upwelling region, which is mainly caused by high equatorial diversity in the Platysceloidea hyperiids. Although this latitudinal pattern was also observed for salps (Macpherson, 2002), it is not the dominant pattern for latitudinal diversity gradients in the pelagic. A bimodal pattern of species richness is most commonly observed, with highest diversity in the subtropical gyres, (slightly) lower diversity in the equatorial upwelling zone, and a sharp decrease in species diversity poleward of the subtropical convergence (e.g., Rutherford et al., 1999; Brayard et al., 2005; Boyce et al., 2008; Dolan and Pierce, 2013). Such a pattern was reported for anthomedusan hydrozoans (Macpherson,

2002), cephalopods (Rosa et al., 2008) as well as for planktonic crustaceans, including euphausiids (Angel, 1997; Tittensor et al., 2010), decapods (Angel, 1997), and ostracods (Angel, 1997; Angel et al., 2007). Some fishes and microplanktonic groups also demonstrate this bimodal pattern, such as tuna and billfish (Boyce et al., 2008), tintinnid ciliates (Dolan and Pierce, 2013) and planktonic foraminifera (Rutherford et al., 1999; Tittensor et al., 2010). Finally, this pattern was observed for shelled pteropods along AMT24, a similar basin-scale transect in the Atlantic Ocean (BurrIDGE et al., in press: Thesis chapter 6). A second latitudinal diversity pattern reported for some pelagic groups is of a broad plateau of species richness across subtropical and tropical waters (e.g., siphonophores and cephalopods; Macpherson, 2002). The Phronimoidea hyperiids in our study demonstrated this diversity plateau, with species richness relatively constant across warm waters of both subtropical gyres and the equatorial region (FIGURE 2B). Collectively, these studies demonstrate that basin-scale latitudinal diversity patterns differ among pelagic groups, and even among different superfamilies within hyperiid amphipods, suggesting that they may result from different drivers.

Because most hyperiid amphipods are commensal or parasitic on gelatinous hosts, their large-scale patterns in distribution, abundance, and diversity are likely driven substantially by host abundance and diversity (e.g., Madin and Harbison, 1977; Laval, 1980; Lavaniegos and Ohman, 1999; Gasca et al., 2007, 2015). In this study, we find some evidence that distribution patterns of hyperiids may be associated with distribution patterns of their respective hosts. However, we know that these fragile gelatinous plankton groups are not sampled adequately with plankton nets. Within Platysceloidea, the superfamily with a high equatorial peak in species diversity, the host-associations appear to be more specific than in the Phronimoidea superfamily, which had a broad warm water plateau in species richness (FIGURE 2B; Harbison et al., 1977, 1978; Madin and Harbison, 1977; Laval, 1980; Gasca et al., 2007, 2015). For example, the Lycaeidae family (Platysceloidea) is strongly associated with salp and pyrosome tunicates (e.g., Harbison, 1976; Madin and Harbison, 1977; Laval, 1980). The Lycaeidae family was most diverse in the equatorial region and contributed to the equatorial species diversity peak for Platysceloidea that was observed in this study (FIGURE 2B; TABLE S1). Likewise, salps show a peak in species diversity in equatorial waters (Macpherson, 2002) and salp blooms have been reported to be associated with increases in primary production (Stone and Steinberg, 2014) and upwelling of nutrients (Li et al., 2011) as occurs in the equatorial upwelling zone. We did not find prior reports in the literature suggesting a higher abundance of siphonophores or ctenophores in the equatorial region that may further explain the high equatorial diversity of Platysceloidea (but see Stemmann et al., 2008, for differences in abundance of gelatinous zooplankton between other oceanic regions worldwide). However, we noticed high abundances of pyrosomes, salps and other gelatinous plankton in the equatorial upwelling region along AMT22 (Peijnenburg and Goetze, unpubl. observations). In contrast, an example of less specific host associations at the family-level can be found in Hyperiidae (Phronimoidea),

with species known to associate with salp tunicates, ctenophores, scyphozoans, and antho- and leptomedusan hydrozoans (e.g., Harbison et al., 1977; Madin and Harbison, 1977; Laval, 1980; Lavaniegos and Ohman, 1999; Kruse et al., 2015). The tropical and subtropical plateau in species diversity of the Phronimoidea superfamily may be linked to this low host specificity.

SPECIES ASSEMBLAGES AND OCEANOGRAPHY

Hyperiid species assemblages were distinct for gyral, equatorial, transitional, and subantarctic stations along AMT22 (FIGURES 4 and 5). The sharpest transition in hyperiid species composition occurred in the South Atlantic Ocean between the southern subtropical convergence and the subantarctic province, located at ~34–38°S. This transition consisted of a sudden drop in species diversity, with *Themisto gaudichaudii* and *Primno evansi* dominating in subantarctic waters (76.9 and 17.9% of the total assemblage; TABLE 2). The location of this transition is similar to that found for pteropods, which also showed dramatic declines in species richness poleward of the convergence zone along a similar AMT transect (AMT24; BurrIDGE et al., in press: Thesis chapter 6). This region is characterized by a shift from oligotrophic waters with a deep DCM (150–200 m) and very low chlorophyll *a* concentrations (<0.6 mg/m³ at the DCM) to well-mixed waters with shallow (<75 m) and high (>0.75 mg/m³) maximum chlorophyll *a* concentrations. We found similar hyperiid species assemblages in the northern and southern subtropical gyres, a pattern also observed for assemblages of pteropods (BurrIDGE et al., in press: Thesis chapter 6), copepod genera (Woodd-Walker et al., 2002), and cephalopod families (Rosa et al., 2008) within the Atlantic, as well as for several groups in the Pacific basin (e.g., Brinton, 1962; Williamson and McGowan, 2010). However, the northern and southern gyre ecosystems are not exact replicates of one another, as was reflected by the slightly lower hyperiid diversity and higher relative species dominance in the southern gyre (FIGURES 2 and S1).

The hyperiid species assemblage in the equatorial region occurred between ~7°N and 8°S, across a narrower latitudinal band than observed in some other zooplankton groups (e.g., Woodd-Walker et al., 2002; Angel et al., 2007; Hirai et al., 2015; BurrIDGE et al., in press: Thesis chapter 6; Goetze et al., in press). Specifically, the location of the northern boundary of the equatorial hyperiid assemblage did not extend as far north as is commonly found for other zooplankton. BurrIDGE et al. (in press: Thesis chapter 6) found a distinct equatorial assemblage between 14°N and 4°S with transitions at 18°N and 8°S for pteropod species along a similar Atlantic transect (AMT24, 2014). Angel et al. (2007) studied the inter-station similarities of ostracod assemblages in the North Atlantic and found that stations at 18°N, 10°N and 0° grouped closely together, suggesting that the equatorial species assemblage extended much farther north than was observed in hyperiids. For copepod genera, the equatorial assemblage occurred between 17.5°N and 7.5°S (Woodd-Walker et al., 2002). This narrower equatorial distribution for hyperiids may be a consequence of their dependence on gelatinous hosts, which serve as a micro-environment over large parts of the hyperiid life cycle (e.g., Laval, 1980).

However, little is known about species diversity and distribution patterns of gelatinous hosts across these Atlantic Ocean provinces (as shown by the distribution of the Jellyfish Database Initiative (JEDI) metadata sets in Condon et al., 2012), impeding our ability to assess whether the boundaries of distinct hyperiid species assemblages reflect those of their gelatinous hosts.

There are several limitations of the sampling in this study, and further work on hyperiids at ocean basin scales is justified. Our material was collected with the primary goal of providing specimens for molecular studies on marine zooplankton, and so while the 200 μm mesh net was handled quantitatively (e.g., calibrated flowmeter mounted in the net), the paired 333 μm mesh bongo net was intended for live collections of larger-bodied animals. Subsequent work should be conducted on a more quantitative collection of material, drawing from the initial taxonomic observations of this study. In addition, more information on the diversity and distribution of gelatinous hosts would enable greater inference from our observations on hyperiids. Although it may not be appropriate to attempt to quantify the gelatinous plankton in our net-collected samples, one fruitful way forward could be to examine the gut contents of hyperiids using a molecular approach in order to establish the taxonomic identities of hyperiid-host relationships (e.g., metabarcoding; Pompanon et al., 2012). Hyperiids often feed on host tissues (Laval, 1980), and DNA sequences from hyperiid stomach contents could reveal host identity in the majority of cases where net-collected animals have been disturbed from their hosts. Similar molecular diet studies have been very informative for detecting novel trophic links in other marine species (e.g., Deagle et al., 2009; Olsen et al., 2014; Albaina et al., 2016).

CONCLUSION

This study is among the first to examine large-scale diversity and distribution patterns of hyperiid amphipods across open waters of the Atlantic, and our data provide important new distributional records across six oceanic provinces. The latitudinal maximum in hyperiid species richness occurred in the equatorial upwelling region, and was largely driven by increases in the diversity of Platysceloidea hyperiids. We also observed a significant positive relationship between species richness and sea surface temperature at the basin scale. The dominant paradigm of a bimodal pattern of species richness in pelagic systems, with maxima in the subtropical gyres, was not supported by our data on hyperiids. Instead we propose that the large-scale patterns of hyperiid diversity are at least partly driven by gelatinous host abundance and diversity. However, limited knowledge of the diversity and distribution of gelatinous zooplankton hosts impedes our inferences regarding drivers of these basin-scale patterns in hyperiids. Species assemblages along AMT22 broadly supported a division into gyral, equatorial, transitional, and subantarctic hyperiid communities, congruent with Longhurst's (1998) biogeochemical provinces. Biogeographic distributions of hyperiids ranged from species that were endemic to specific regions (e.g., *Vibilia borealis*, *Eupronoe minuta*, *Hyperietta vosseleri*, *Vibilia stebbingi*), to species that occurred across broad warm

water ranges (e.g., *Hyperietta stephensi*). Some species occurred in warm-, intermediate, as well as cold water regions (e.g., *Vibilia armata*, *Primno evansi*) often with disjunct distribution patterns. Such broadly distributed species may represent assemblages of cryptic or morphologically similar species, and would be interesting target species for future phylogeographic and taxonomic studies.

ACKNOWLEDGEMENTS

We thank the officers and crew of the RRS James Cook for supporting our zooplankton collections, K. van den Berg and K. Beentjes for help with imaging of hyperiid specimens, and J. Huisman for comments on the manuscript. This work was supported by a Netherlands Organisation for Scientific Research (NWO) cruise participation grant and VENI grant 863.08.024 to K.T.C.A. Peijnenburg. E. Goetze and the fieldwork for this study were supported under National Science Foundation (USA) grants OCE-1029478 and OCE-1338959. Plankton collections for this study were partially supported by the UK Natural Environmental Research Council National Capability funding to Plymouth Marine Laboratory and the National Oceanography Centre, Southampton. This is contribution number 304 of the Atlantic Meridional Transect Programme.

Discussion

To track the effects of ocean change on pelagic species diversity and distribution patterns, it is essential to better understand how current biodiversity evolved, what part of the biodiversity is where, and how closely related species can be distinguished. In this thesis, I aimed to better understand the diversity, distribution, and evolution of three groups of marine zooplankton. The focus of my PhD research was on pteropods (Chapters 2-6), but I also investigated the diversity and distribution patterns of another group of planktonic gastropods: the shelled heteropods (Chapter 6), and of a conspicuous group of planktonic arthropods: the hyperiid amphipods (Chapter 7). In doing so, the work reported in this thesis has contributed to several public reference databases containing genetic, biogeographic, and morphometric data of these taxa. One of the core challenges of my research was to accurately identify species and hence, I discuss the pros and cons of different methods I used or which could be applied in future research. I also discuss the potential of using pteropods as indicators of ocean acidification, including what open questions still need to be addressed and recommendations for future research.

IDENTIFYING SPECIES IN THE OPEN OCEAN

The identification of species in my PhD research was largely based on an integrative approach. I used qualitative morphological identification based on taxonomic keys in Chapters 2, 6, and 7, applied quantitative geometric morphometric methods in Chapters 3, 4, and 5, and used DNA sequencing of specific genes to assess genetic relatedness in Chapters 2-5. Furthermore, I also used geographic information where available (Chapters 2-7). Species diversity in the plankton has likely been underestimated based on morphology only. Hence, genetic methods such as DNA barcoding are useful in revealing additional diversity, but they do not come without pitfalls (Bucklin et al., 2011, 2016; Peijnenburg and Goetze, 2013).

DNA barcoding is the use of short DNA sequences for species recognition and discrimination and has accelerated the rate of discovery of taxonomic diversity (Hebert et al., 2003). Barcoding of zooplankton taxa revealed additional clades that may represent new or previously discounted zooplankton species (Goetze, 2010; Blanco-Bercial et al., 2014; Cornils and Held, 2014; Laakman and Holst, 2014; Hirai et al., 2015a). Cytochrome Oxidase I (COI) is the most frequently used gene in animals and there is an extensive database available for comparison, but for zooplankton taxa it is very incomplete and samples are often not identified to species level (Benson et al., 2013). For COI, genetic distances are typically <3% within zooplankton species and >10% between species (Bucklin et al., 2011). However, a universal barcode to identify species defined by a standard barcoding gap of at least 2% divergence between COI sequences is not always applicable across different zooplankton groups. According to Hebert et al. (2003), 94.1% of the Cnidaria species possessed less than 2% of pairwise sequence divergence versus 1.9% of the species in other taxonomic groups, such as Annelida, Arthropoda, Chordata, Cnidaria, Mollusca, Nematoda, and Platyhelminthes. Another exceptional group in the marine zoo-

plankton are chaetognaths. A recent study by Marlétaz et al. (2017) showed that sequence divergence within a single population of the species *Sagitta elegans* could be as high as 17.8% for COI and up to 20.8% for all mitochondrial genes combined.

Defining a hard barcoding gap is difficult in pteropods because genetic differences between morphologically distinct taxa can be highly variable. Hence, an integrative taxonomic approach was needed to more accurately assess species boundaries. I applied this approach to assess species boundaries in *Cuvierina* and *Diacavolinia* (Chapters 3-5) based on a combination of two-dimensional geometric morphometric analyses of their shell shapes and DNA sequences of mitochondrial COI and nuclear 28S genes. For *Cuvierina* species, I additionally applied Ecological Niche Modelling (ENM) to quantitatively estimate the ecological tolerances of distinct morphotypes. Standard DNA barcoding failed to detect some incipient *Cuvierina* species, such as *C. cancapae*, which were found to be morphologically and ecologically different. DNA barcoding revealed three major mitochondrial clades that each would represent one species according to the barcoding gap species concept, with average pairwise genetic distances of 4.5-5.1% between clades (Chapter 3). The first clade represents specimens from the Atlantic Ocean. It consists of two morphotypes, *C. atlantica* and *C. cancapae*, differing in both shell ornamentation and shell shape, but which were not distinguished based on COI sequences (average pairwise genetic distance between morphotypes was 2.0%, similar to the genetic distance within morphotypes). Hence, we concluded that these morphotypes probably diverged recently. The clade representing the Indo-Pacific Ocean comprises *C. columnella*, *C. urceolaris*, and *C. tsudai* individuals sampled predominantly from the North Pacific Ocean. These morphotypes are closely related according to their COI sequences (average pairwise genetic distance was 1.7%) but they differ in shell ornamentation and shell shape. However, because there were very few genetic samples for *C. columnella* and *C. urceolaris*, I concluded that they should remain separate species based on their remarkably different shell shapes and ornamentations compared to *C. tsudai*. *Cuvierina pacifica* (0.8% average pairwise genetic distance) sampled exclusively in the South Pacific gyre differed both morphologically and genetically from the other *Cuvierina* species and was distinguished as a separate, third genetic clade based on COI sequences (Chapters 3 and 4). Former *C. pacifica* individuals that belong to the same Indo-Pacific genetic clade as *C. columnella* and *C. urceolaris* were described as the new species *C. tsudai* in Chapter 4.

COI sequences of *Diacavolinia* pteropods were highly diversified (Chapter 5). Pairwise genetic distances between mitochondrial clades were much larger for *Diacavolinia* (18.6-43.8% average pairwise genetic distance) than for *Cuvierina* taxa (4.5-5.1%), but pairwise differences within mitochondrial clades were comparable for *Diacavolinia* and *Cuvierina* (0.2-6.3% and 0.8-2.0% average pairwise genetic distance, respectively). Based only on COI, one could doubt whether *Diacavolinia* represents a single genus because pairwise genetic differences between clades were much larger than within other pteropod genera. However, results of the more conservative nuclear ribosomal genes 28S (Chapters 2 and 5) as well as 18S (Chapter 2) show that

Diacavolinia taxa are monophyletic and are all nested within *Cavolinia* rendering this latter genus paraphyletic. Moreover, COI sequences could not be obtained for all *Diacavolinia* taxa and not all taxa were resolved based on 28S sequences. Hence, it is clear that a lot of genetic diversity exists within *Diacavolinia* and *Cavolinia* clades, however, their taxonomy is still unresolved. Adding geometric morphometric information to the available genetic information proved useful in assessing species boundaries within *Diacavolinia*, resulting in the confirmation of described taxa or discovery of new taxa (Chapter 5). Using a species hypothesis based on a combination of data types, I found that no *Diacavolinia* species were shared between the Atlantic and Indo-Pacific oceans, two species were supported in the Atlantic Ocean in contrast to eight currently described, and a maximum of 11 species was present in the Indo-Pacific Ocean, comprising 13 of the currently described species. However, ENM was not applied to *Diacavolinia* taxa because some specimens could not be assigned with confidence to a species, for example, when no genetic and too little morphological information was available. Additionally, some species were extremely rare and did not allow for such methods. In Chapter 5, I found five such taxa, of which only one to three specimens were ever sampled at single locations in the world's oceans during multiple sampling expeditions between 1909 and 2012.

METHODOLOGICAL ASPECTS

Throughout this thesis, specimens from the natural history collections at Naturalis Biodiversity Center in Leiden and the Zoological Museum of Copenhagen provided an essential initial framework for assessing species boundaries and represented a substantial source of information (Chapters 3-5). Historical samples from the 19th and 20th centuries, including specimens from the Danish DANA expeditions, which were thoroughly studied by A. Janssen (e.g., Janssen, 2005, 2007, 2010, 2012; Cahuzak and Janssen, 2010), were essential for use as reference samples and for increasing total sampling coverage for geometric morphometric purposes across the global ocean, especially in the Indian Ocean (e.g., Schmidt, 1934). Combined with fresh specimens for which morphometric as well as genetic information could be obtained, historical museum specimens enabled accurate assessment of species boundaries and matching of *Diacavolinia* morphotypes to actual species names. Museum samples were available for 23 of the 24 *Diacavolinia* taxa described by Van der Spoel et al. (1993), including holo- and/or paratypes for 14 taxa.

Computed tomography (CT) scanning allows the reconstruction of shells and internal structures at micrometer scale in 3D and the measurement of shell thickness, volume, density, and shape (Liew, 2014; Manno et al., 2017). Three-dimensional geometric morphometric analyses may be better able to distinguish between taxa than the two-dimensional geometric morphometric analyses used in this thesis (Chapters 3-5). However, it is more time-consuming to apply 3D compared to 2D morphometrics and standard workflows for data analysis are not available yet. Hence, depending on the research purpose, I do not think that 3D morphometric methods should completely replace 2D geometric morphometric methods.

In recent years, high-throughput or next-generation sequencing (NGS) methods have rapidly developed and have generated large volumes of genomic data on non-model organisms (Taylor and Harris, 2012). NGS-based DNA sequencing methods can be more sensitive than traditional Sanger sequencing of a few selected genes, and hence, would probably better resolve recently diverged or incipient species. For example, I hypothesize that for *Cuvierina*, additional genetic markers in the form of Single Nucleotide Polymorphisms (SNPs) scattered across the genome will provide enough information to distinguish genetically between ecologically distinct morphotypes (Chapter 3). Additionally, such NGS-based methods would circumvent the problem of specimens that did not amplify for particular genetic markers. Null amplifications of COI were a problem for one *Diacavolinia* clade and were probably due to mutations in primer regions (Chapter 5). Furthermore, another NGS-based technique, such as RNA-sequencing, could generate large amounts of transcriptomic data. These would allow phylogenomic analyses including genetic information of >1000 protein-coding genes, which could improve our understanding of the evolutionary history of pteropods. This would probably result in better resolution of higher taxonomic levels in the phylogeny of pteropods, such as the relation between the Euthecosomata, Pseudothechosomata, and Gymnosomata suborders. Their phylogenetic relationships remained unresolved based on three genetic markers (Chapter 2). It may also better resolve relationships between coiled and uncoiled euthecosome genera. The use of many slowly evolving protein-coding genes rather than a small subset of genes would homogenize long branches due to high rate variation within and between taxa, as was the case for *Limacina bulimoides* and *Heliconoides inflatus* (Chapter 2).

Metabarcoding is another emerging NGS method, used for large-scale taxonomic identification of complex samples via analysis of one or more homologous DNA regions (barcodes). It basically combines DNA-based identification methods with high throughput sequencing (Bucklin et al., 2016). Applications include estimation of zooplankton community composition and species discovery (Lindeque et al., 2013; De Vargas et al., 2015; Pearman and Irigoien, 2015), community composition of specific taxa (Hirai et al., 2015b; Wu et al., 2015), and estimation of spatio-temporal turnover (Brannock et al., 2016; Chain et al., 2016).

There are many advantages to the use of metabarcoding for identifying species in the marine zooplankton especially because large amounts of data can be generated in an efficient way, which has the potential of broadening the understanding of the diversity of different pelagic groups, assessment of ecosystem health, detection of impacts of climate change, and characterization of food webs (Bucklin et al., 2016; Leray and Knowlton, 2016). However, metabarcoding also has limitations compared to morphology with respect to identifying species in the marine zooplankton assemblage.

First, metabarcoding of marine zooplankton is hindered by a lack of taxonomic identification at lower taxonomic levels due to gaps in reference databases, reducing the confidence in assigning operational taxonomic units (OTUs) to species (Bucklin

et al., 2016; Leray and Knowlton, 2016). Hence, although metabarcoding can provide a broad assessment of zooplankton diversity, it cannot simply replace morphological species identifications and there is an urgent need for updating and building of reference databases for the marine zooplankton assemblage.

Second, although morphological analysis may underestimate biodiversity in the global ocean compared to metabarcoding because not all plankton taxa can be distinguished morphologically, metabarcoding may also fail to amplify certain species or even entire groups because of mutations in the primer regions, as was the case for certain *Diacavolinia* taxa (Chapter 5). For example, a comparative study between metabarcoding and microscopy demonstrated a high correspondence in community composition for zooplankton, but not for phytoplankton (Abad et al., 2016).

Third, unlike metabarcoding, species identification based on morphology enables the estimation of species abundances, because individual specimens are preserved and can be counted. Quantitative zooplankton species identification based on morphology enables conversion to biomass (Chapter 6). In metabarcoding, the number of sequence reads associated with an OTU can potentially estimate biomass (Lindeque et al., 2013). Several studies have shown a positive correlation between number of sequence reads and dry weight of the taxon (e.g., Hirai et al., 2015c). Sun et al. (2015) demonstrated a correspondence between low-abundance sequence reads and low-abundance species. However, these findings should be treated with caution because metabarcoding not always corresponds with morphological species abundance data (e.g., Mohrbeck et al., 2015). The relation between number of sequence reads and biomass is probably not linear and will be biased by species-specific differences in copy numbers of 28S and 18S in the genome. Hence, state-of-the-art metabarcoding remains at best a semi-quantitative method for assessing species abundances (Bik et al., 2012).

Fourth, diversity estimates based on metabarcoding result in a number of OTUs but it is unclear how this number relates to actual species diversity. This depends on the chosen similarity threshold based on the marker of choice, its sequence length, and intra- and interspecific degree of conservation for assignment of sequences to OTUs. Although assessing taxonomic diversity based on similarity thresholds is also possible when reference taxonomic information is not available, it is not clear how this number relates to the actual number of biological species (Brown et al., 2015). In this sense, the problem with fixed barcoding gaps persists. A threshold based on high similarity may overestimate taxon richness, and any threshold assumes that intraspecific variation is approximately equally distributed across taxonomic groups. Hence, an integrative approach remains critically important for taxonomic identification of new, closely related taxa based on combined information including biogeography and ecology.

PTEROPODS AS INDICATORS OF OCEAN ACIDIFICATION

In recent years, pteropods have gained considerable attention because of their potential vulnerability to ocean acidification (e.g., Fabry et al., 2008). However, the

usefulness of pteropods as potential indicators of the effects of ocean acidification is compromised by limited historical context for understanding species-specific long-term exposure to variation in ocean chemistry (but see Janssen et al., 2016). The degree of pteropod vulnerability to ocean acidification is currently debated (Bednaršek et al., 2016a; Peck et al., 2016). Based on observations of *Limacina helicina* pteropods, Peck et al. (2016) conclude that shell dissolution is only happening if the periostracum, the outer protective layer, is damaged. If this is true, shelled pteropods may not be as vulnerable to ocean acidification as currently thought (e.g., Bednaršek et al., 2016b). All in all, future work may provide more insights into the sensitivity of different pteropod species to ocean acidification as well as the role of the periostracum.

A number of open questions regarding the effects of ocean acidification on shelled pteropods are discussed in the review paper by Manno et al. (2017). Some are addressed in this thesis. First, it is often still unknown whether genetically distinct forms can be morphologically separated and the other way round, and whether regional differences within pteropod species could be responsible for distinct physiological responses to ocean acidification. To improve the accuracy of knowledge of the taxonomy, evolution, and biogeography of pteropods, an evolutionary framework of pteropods was constructed (Chapter 2) and an integrative taxonomic approach was applied to delimit species within the pteropod genera *Cuvierina* (Chapters 3 and 4) and *Diacavolinia* (Chapter 5). Second, it would be informative to know species diversity and abundance patterns in relation to oceanographic parameters such as temperature, chlorophyll *a*-concentrations, and carbonate chemistry. For Chapter 6, species diversity and abundance data as well as water column properties were obtained by participation in a multidisciplinary oceanographic expedition across the Atlantic Ocean. Participation in this expedition led to new insights in species distributions and abundances based on ecological preferences, as well as in the interplay between species assemblages and water column properties, such as a positive correlation between species diversity and water temperature (AMT24; Rees et al., 2017). Ocean change may affect the distributions and abundances of pteropod species, which can be assessed by resampling zooplankton communities along a similar transect in the future.

Because different pteropod growth stages may have different tolerances to ocean acidification, historical records can be a valuable contribution to our understanding of the controls of ocean acidification on growth stage. To understand the historical context of ocean acidification and to monitor the potential effects of ocean change on shell mineralization, specimens from different time spans may be obtained from museum collections (e.g., Howes et al., 2017) or from sediment cores (e.g., Wall-Palmer et al., 2013). Although *Cuvierina* and *Diacavolinia* specimens obtained from museum collections were not used as such in Chapters 3-5, this is possible in future work. In a comparison of Mediterranean pteropod shell biometrics, thicker shells were observed in historical samples (1910 and 1921) compared to recent samples (2012) for Mediterranean *Cavolinia inflexa* and

Styliola subula (Howes et al., 2017). Time series in the Mediterranean Sea covering the period 1967-2003 showed a pH decline of 0.05 units, but this decline did not cause a decrease in local pteropod abundances (Howes et al., 2015). To study the in-life shell dissolution of pteropods from the Late Pleistocene, Wall-Palmer et al. (2013) used fossil *Heliconoides inflatus* specimens not affected by post-depositional shell dissolution. Marine sediment cores proved useful in determining that high in-life dissolution of shells due to low aragonite saturation levels in the past was accompanied by smaller shell sizes, indicating a reduction in calcification rate.

Apart from time series of shell biometrics using historical samples, shell dissolution in undersaturated basins or simulated laboratory conditions may be another measurement of the effects of ocean acidification on pteropods. Several experimental studies have been conducted to understand the consequences of short-term exposure to elevated CO₂ conditions. In-situ studies and laboratory incubations simulating the effects of future atmospheric CO₂ scenarios have mainly focused on shelled pteropods, but heteropods have received little attention thus far (Wall-Palmer et al., 2016). Reported potential implications of ocean acidification on shelled pteropods include shell degradation, reduced shell calcification rates, abnormal shell growth, metabolic suppression, and ultimately, reduced survival (Comeau et al., 2009, 2010a,b, 2012; Lischka et al., 2011; Bednaršek et al., 2012a,b; Lischka and Riebesell, 2012; Maas et al., 2012; Manno et al., 2012, 2015; Seibel et al., 2012; Gazeau et al., 2013). Effects of ocean acidification on larval stages of pteropods may be even more severe than effects on adults (Comeau et al., 2010a). An experiment in which larvae of Mediterranean *Cavolinia inflexa* were maintained at pH 8.1, 7.8, and 7.5 demonstrated that shells became malformed at pH 7.8, and that larvae did not make shells at pH 7.5 (Comeau et al., 2010a). However, because pteropods are notoriously difficult to maintain in the laboratory, resultant high mortality rates and unnatural behaviors may bias experimental study outcomes (Howes et al., 2014). Effects of culturing pteropods may be the inability of adults to feed, rapid sinking when not actively swimming, and shell damage during sampling (Peck et al., 2016; Manno et al., 2017). These issues require careful consideration in future designs for pteropod culturing, which are still developing (Howes et al., 2015).

Effects of ocean acidification on pteropod shells have also been examined using live animals collected directly from their natural environments (Bednaršek et al., 2012a, 2014, 2015). These authors demonstrated that impacts of ocean acidification on shell mineralization were also occurring in populations under supersaturated conditions in the Southern Ocean (Bednaršek et al., 2012a). This implies that regional declines of pteropod populations may occur sooner than currently projected. Pteropod studies from the California Current Ecosystem (CCE) indicated decreasing habitat suitability due to ocean acidification (Bednaršek et al., 2014, 2015). However, future experiments should consider that shell mineralization is not only affected by ocean acidification, but also by other synergistic stressors, including ocean warming, deoxygenation, and increased stratification (Kroeker et al., 2017; Manno et al., 2017).

Transcriptome-wide analyses are increasingly applied to understand the differences in physiological responses of pteropod species and populations to the effects of ocean acidification (Maas et al., 2015; Moya et al., 2016). For example, a study of the physiological response of *Clio pyramidata* to a 10-h exposure to elevated CO₂ (800 ppm) demonstrated differential gene expression patterns compared to ambient conditions (380 ppm; Maas et al., 2015). Some genes associated with aerobic metabolism were down-regulated, and some genes that may be associated with biomineralization were up-regulated. During a 3-day experiment, *Heliconoides inflatus* demonstrated a decrease in gross calcification in response to acidified conditions (pH 7.9) compared to control treatments (pH 8.1) despite up-regulation of genes potentially involved in calcification (Moya et al., 2016). This reflects the inability of pteropods to maintain calcification rates under acidified conditions. Moreover, a large number of genes related to nervous system structure and function were also up-regulated, potentially leading to altered behavior.

In conclusion, my thesis has revealed substantial genetic and taxonomic diversity in the marine zooplankton assemblage, with a special focus on pteropods. This taxonomic diversity is the result of their evolutionary history and ecological responses to environmental variation. I found that different species of pteropods and distinct species assemblages occur across distinct biogeochemical provinces of the global ocean. This supports the idea that there may be considerable biological variation in the sensitivities of these calcifying organisms to ocean acidification (Fabry et al., 2008). Hence, my studies urge for an accurate taxonomic resolution to study the response of pteropods, and more generally, of other marine zooplankton to environmental pressures. Biological variation within and among species should be taken into account in projections of the response of marine ecosystems to global change.

Summary

MARINE BIOGEOGRAPHY AND EVOLUTION: DIVERSITY PATTERNS OF PLANKTONIC GASTROPODS AND AMPHIPODS

Current changes in the oceans, including global warming and ocean acidification, are partially caused by human activity, unlike earlier episodes of change throughout geological history. Understanding and forecasting the responses of marine organisms to these changes is top priority for scientists, managers and policy makers. Yet, relatively little is known of the effects of ocean change on marine zooplankton. Ocean change affects species diversity and distributions, but different zooplankton taxa may not be equally affected. This thesis aims to fill this knowledge gap by contributing information regarding the taxonomy, genetic diversity, and biogeography of several selected marine zooplankton groups, providing baseline information that is needed to track the effects of ocean change on marine zooplankton. The study organisms in this thesis represent two groups of planktonic gastropods: pteropods (sea butterflies and sea angels) and heteropods (sea elephants), and a group of crustaceans: the hyperiid amphipods. Pteropods are uniquely suitable for the study of long-term evolutionary processes in the open ocean because their aragonite shells provide a good fossil record. They have been proposed as bioindicators to monitor the impacts of ocean acidification. Heteropods are another group of pelagic gastropods that independently colonized the pelagic. They are visual predators that prey upon shelled pteropods. Shelled heteropods have received little attention relative to pteropods, but are probably equally vulnerable to the effects of ocean acidification. Hyperiiids represent a highly diverse and abundant group and are often commensals and parasitoids of gelatinous plankton. They play unique and important ecological roles in pelagic foodwebs.

The major questions that are being addressed in this thesis are:

- (1) How can closely related pteropod species be distinguished?
- (2) When did current pteropod biodiversity evolve?
- (3) Which pteropod, heteropod, and hyperiid amphipod species are where in the Atlantic Ocean?

HOW CAN CLOSELY RELATED PTEROPOD SPECIES BE DISTINGUISHED?

To be used as bioindicators of ocean acidification, it is important to accurately assess species boundaries of pteropods, because different species are expected to respond differently to ocean changes. An integrative taxonomic approach based on combining morphological, genetic, and geographic information was applied to assess species boundaries in the circumglobal pteropod genera *Cuvierina* and *Diacavolinia* (Chapters 3, 4, and 5). The approach combined molecular phylogenetic analyses based on Cytochrome Oxidase I (COI) and 28S DNA sequences, geometric morphometric analyses of shells, as well as ecological niche modelling (only in Chapter 3). Museum samples provided an essential initial framework for assessing

species boundaries based on morphological information and a substantial source of information for increasing geographic coverage.

Based on geometric morphometric analyses, six morphotypes were distinguished within the genus *Cuvierina* (Chapter 3). These morphotypes had distinct ecological preferences and belonged to three major genetic clades. Using a fossil-calibrated phylogenetic analysis, it was estimated that these clades separated in the Late Oligocene and Early to Middle Miocene. Based on these findings, two previously distinguished subgenera of *Cuvierina* were rejected and a new species endemic to the Pacific Ocean was described (Chapter 4). Current consensus is that there exist two Atlantic, two Pacific and two Indo-Pacific *Cuvierina* species. These species can generally be distinguished based on their differences in shell shape and size, but more information is preferred to more confidently confirm their status as species. Because not all taxa were distinguished based on COI sequences, the number of genetic markers should be increased.

Diacavolinia is the most speciose genus of shelled pteropods with 24 described taxa. The measurements of several hundreds of freshly-collected and museum specimens including type specimens provided evidence for a reduction in the number of species to a maximum of 13 species (Chapter 5). The most important biogeographic barriers were between the Atlantic and Indo-Pacific oceans, and between the East and Central Pacific. These barriers are well-known for other zooplankton groups as well.

All in all, an integrative approach proved successful in distinguishing between pteropod species, although additional molecular markers are needed to more accurately distinguish between closely related taxa, as was demonstrated for *Cuvierina* and *Diacavolinia*. Moreover, some rare *Diacavolinia* taxa currently lack morphological and/or genetic information. Hence, additional sampling efforts are still needed, especially in the highly diverse Indo-Australian Archipelago and the East Pacific Ocean.

WHEN DID CURRENT PTEROPOD BIODIVERSITY EVOLVE?

Combined with molecular methods for phylogenetic inference, the fossil record improves our understanding of the evolution of pteropods by providing a framework of ages for certain shelled taxa. The phylogenetic relationships of 55 pteropod species (euthecosomes, pseudothecosomes, and gymnosomes) collected from all ocean basins and spanning the diversity of the group were inferred using time-calibrated molecular phylogenies based on combined analyses of COI, 28S, and 18S gene sequence data and information of the fossil record (Chapter 2). However, the phylogenetic relationships between (sub)orders euthecosomes, pseudothecosomes, and gymnosomes were not resolved based on the available information. The uncoiled euthecosomes were monophyletic, and within this group, *Creseis* was monophyletic, as well as all other uncoiled genera together. Most uncoiled genera were also supported, but *Clio* was polyphyletic, and *Diacavolinia* grouped within *Cavolinia*, rendering the latter genus paraphyletic. The coiled euthecosomes were not monophyletic contrary to the accepted morphology-based taxonomy, but indi-

vidual genera were. With the first occurrence of coiled euthecosomes estimated at 79–66 million years ago (mya), it was inferred that uncoiled euthecosomes evolved 51–42 mya and that most extant uncoiled genera originated 40–15 mya, with *Creseis* as the earliest diverging lineage at 41–38 mya. These findings are congruent with a molecular clock analysis using the Isthmus of Panama formation as an independent calibration. Although not all phylogenetic relationships could be resolved, the new data on the diversity and evolution of pteropods are an essential first step for their use as bio-indicators of the ongoing effects of ocean acidification. To improve phylogenetic resolution, especially at higher (order or suborder) levels, it will be necessary to increase the number of genetic markers substantially (e.g., by applying a phylogenomic approach). For future studies, it is also necessary to increase taxon sampling of pseudotheosome and gymnosome taxa, which were underrepresented in this study.

WHICH PTEROPOD, HETEROPOD, AND HYPERIID AMPHIPOD SPECIES ARE WHERE IN THE ATLANTIC OCEAN?

The distributions and abundances of many marine zooplankton species are still poorly known. Large collections of meso- and macrozooplankton material collected from the upper 300 m along a basin-scale meridional transect in the Atlantic Ocean between 46°N and 46°S contributed to the characterization of the diversity and distribution of pteropods, heteropods, and hyperiid amphipods (Chapters 6 and 7). Species richness of pteropods and heteropods was highest in the stratified (sub)tropical waters between ~30°N and ~30°S, a diversity pattern similar to that reported for other pelagic taxa (e.g., decapods, ostracods, and foraminifera) (Chapter 6). The diversity of pteropods and heteropods was lowest just south of 40°S. Along a similar transect, maximum species and genus richness of hyperiids occurred in the equatorial upwelling region between 7°N and 8°S (Chapter 7). The observations of equatorial instead of subtropical maxima in species and genus richness for hyperiids suggest that the mechanisms controlling diversity in this group are distinct from other zooplankton groups. These are probably influenced by the distribution and diversity of gelatinous hosts for hyperiids. The distributions of communities of pteropods, heteropods, and hyperiids were largely congruent with Longhurst's biogeochemical provinces. Repeated zooplankton sampling combined with environmental data collected along similar transects will be crucial to monitor changes in species diversity and distribution patterns in response to ocean change.

FUTURE DIRECTIONS

Integrative taxonomy offers a more comprehensive framework for testing species hypotheses than DNA barcoding alone, because diverse and sometimes incomplete character and data types can be combined, and because the sole use of genetic information may sometimes fail to delimit actual species (Chapter 8). Novel research tools, despite their pitfalls, can help species identification and improve our evolutionary understanding of marine zooplankton. Three-dimensional geo-

metric morphometric analyses may better distinguish between taxa than the two-dimensional geometric morphometric analyses used in this thesis. Next-generation sequencing of genomes may better resolve species boundaries and phylogenetic relationships than traditional Sanger sequencing of a few selected genes. Metabarcoding studies based on next-generation sequencing may improve our understanding of zooplankton communities not only in the epipelagic, but also at greater depths, of which still little is known. Furthermore, these methods may be applied to monitor seasonal variation as well as long-term changes in zooplankton communities in response to, e.g., climate change.

All published papers and data supporting the results of this thesis are freely available online, stored in the Dryad online repository and GenBank.

Samenvatting

MARIENE BIOGEOGRAFIE EN EVOLUTIE: DIVERSITEITSPATRONEN VAN PLANKTONISCHE SLAKKEN EN VLOKREEFTEN

De huidige veranderingen in de oceaan, zoals opwarming en oceaanverzuring, worden gedeeltelijk veroorzaakt door de mens, en zijn daarmee anders dan eerdere grootschalige veranderingen in de geologische geschiedenis van onze planeet. Het begrijpen en voorspellen van het effect van deze veranderingen heeft hoge prioriteit voor wetenschappers en beleidsmakers. Er is echter betrekkelijk weinig bekend over de effecten van deze veranderingen op het dierlijke plankton (ofwel zoöplankton) in zee, de organismen die aan de basis staan van vrijwel alle mariene voedselketens. Grootschalige verandering van de oceaan heeft invloed op de diversiteit en verspreidingspatronen van soorten, met verschillende effecten op verschillende groepen zoöplankton. Dit proefschrift onderzoekt de taxonomie, genetische diversiteit, en soortensamenstelling van enkele groepen marien zoöplankton en voorziet daarmee in basiskennis die nodig is om de effecten van verandering van de oceaan op marien zoöplankton te kunnen registreren. De onderzoeksorganismen in dit proefschrift zijn planktonische gastropoden (slakjes): de pteropoden (zeevlinders en zee-engelen) en heteropoden (zeeolifanten), alsook een groep crustaceeën (kreeftachtigen): de hyperiide amfipoden (vlokreeftjes). Pteropoden zijn bijzonder geschikt voor het bestuderen van langdurige evolutionaire processen in de open oceaan omdat hun schelpjes kunnen fossiliseren. Ze staan wereldwijd in de belangstelling als mogelijke bio-indicatoren om het effect van oceaanverzuring op kalkvormende organismen te kunnen meten. Heteropoden zijn een andere groep planktonische gastropoden die onafhankelijk de open waterkolom hebben gekoloniseerd. Het zijn visuele roofdieren en hun voedsel bestaat voornamelijk uit zeevlinders. Heteropoden hebben tot dusver minder aandacht gekregen van oceaanwetenschappers dan pteropoden, maar zijn waarschijnlijk even kwetsbaar voor de effecten van oceaanverzuring. Hyperiidien zijn een zeer diverse en veelvoorkomende groep amfipoden in het plankton en ze hebben vaak een parasitaire relatie met gastheersoorten zoals salpen. Ze spelen een unieke ecologische rol in voedselketens in de oceaan.

De belangrijkste vragen die in dit proefschrift aan bod komen zijn:

- (1) Hoe kunnen nauw verwante soorten pteropoden worden onderscheiden?
- (2) Wanneer is de huidige diversiteit aan pteropoden ontstaan?
- (3) Welke soorten pteropoden, heteropoden en hyperiidien bevinden zich waar in de Atlantische Oceaan?

HOE KUNNEN NAUW VERWANTE SOORTEN PTEROPODEN WORDEN ONDERSCHIEDEN?

Om pteropoden te kunnen gebruiken als bio-indicatoren voor oceaanverzuring is het belangrijk om hun soortsgrenzen in kaart te brengen, want verschillende soorten kunnen op een verschillende manier reageren op veranderingen in de oceaan.

Een gecombineerde taxonomische benadering gebaseerd op zowel morfologische als genetische en geografische informatie is toegepast om soortsgrenzen te bepalen in de tropische en subtropische pteropodengenera *Cuvierina* en *Diacavolinia* (Hoofdstukken 3, 4 en 5). Deze aanpak omvatte moleculair fylogenetische analyses gebaseerd op DNA sequenties van de Cytochrome Oxidase I (COI) en 28S genen, geometrisch morfometrische analyses van schelpjes en het modelleren van ecologische niches (alleen in Hoofdstuk 3). Museummateriaal vormde de basis voor het bepalen van soortsgrenzen gebaseerd op morfologische informatie en was een belangrijke bron van informatie voor een betere geografische verspreiding van monsters.

Zes morfotypen van het genus *Cuvierina* konden worden onderscheiden gebaseerd op geometrisch morfometrische analyses van hun schelpjes (Hoofdstuk 3). Deze zes morfotypen hadden duidelijke ecologische voorkeuren en vormden samen drie genetische groepen. Volgens de evolutionaire stamboom aan de hand van fossielen en DNA zijn deze groepen ontstaan in het Laat-Oligoceen en Vroeg-tot Midden-Mioceen. Aan de hand van deze bevindingen werden twee voorheen gescheiden subgenera van *Cuvierina* verworpen. Ook werd een nieuwe soort beschreven die alleen voorkomt in de Pacifische Oceaan (Hoofdstuk 4). De huidige consensus is dat er twee Atlantische, twee Pacifische en twee Indo-Pacifische soorten *Cuvierina* bestaan. Deze soorten kunnen over het algemeen onderscheiden worden gebaseerd op hun verschillende schelpvormen en -afmetingen, maar meer informatie is wenselijk om hun soortenstatus verder te onderbouwen.

Diacavolinia is met 24 beschreven taxa het meest soortenrijke genus van de pteropoden met schelp. Metingen aan enkele honderden recent verzamelde of uit museumcollecties afkomstige individuen, waaronder type exemplaren, vormden bewijs voor een vermindering van het aantal soorten tot maximaal 13 (Hoofdstuk 5). De belangrijkste biogeografische barrières bevonden zich tussen de Atlantische en Indo-Pacifische oceanen en tussen de oostelijke en centrale Pacifische Oceaan. Deze barrières zijn ook beschreven aan de hand van verspreidingspatronen van andere zoöplanktongroepen.

Over het algemeen was de gecombineerde taxonomische aanpak succesvol in het onderscheiden van pteropodensoorten, maar meer moleculaire informatie is nodig om nauw verwante soorten nog beter te kunnen onderscheiden, zoals blijkt voor *Cuvierina* en *Diacavolinia* soorten. Bovendien is er voor sommige zeldzame *Diacavolinia*-soorten nog geen morfologische en/of genetische informatie beschikbaar. Daarvoor zijn meer samples nodig, vooral uit de zeer diverse Indo-Australische Archipelago en de Oost-Pacifische Oceaan.

WANNEER IS DE HUIDIGE DIVERSITEIT AAN PTEROPODEN ONTSTAAN?

Fossielen bieden een leeftijdsreferentie voor bepaalde pteropodensoorten. Dankzij fossielen en gecombineerde analyses van COI, 28S en 18S sequenties konden de fylogenetische relaties van 55 pteropodensoorten (euthecosomen, pseudothecosomen en gymnosomen), verzameld uit alle oceanen en representatief voor de diversiteit van de groep, worden afgeleid (Hoofdstuk 2). De fylogenetische rela-

ties tussen de (sub)orders euthecosomen, pseudotheicosomen en gymnosomen konden niet worden opgelost op basis van de beschikbare informatie. De ongewonden euthecosomen vormden een monofyletische groep, en binnen deze groep was *Creseis* monofyletisch, net als alle andere ongewonden genera bij elkaar. De meeste andere ongewonden genera werden ook ondersteund, maar *Clio* was polyfyletisch, en *Diacavolinia* groepeerde binnen *Cavolinia*, waarmee de laatste para-fyletisch is. De gewonden euthecosomen waren niet monofyletisch, in tegenstelling tot de geaccepteerde, op morfologie gebaseerde taxonomie, maar individuele genera waren dat wel. In combinatie met het eerste fossiel van een gewonden euthecosoom van ca. 79–66 miljoen jaar oud kon worden afgeleid dat de ongewonden euthecosomen 51–42 miljoen jaar geleden evolueerden en dat de meeste huidige genera 40–15 miljoen jaar geleden ontstonden, met *Creseis* als het oudste genus van 41–38 van miljoen jaar oud. Deze bevindingen komen ongeveer overeen met een moleculaire klok gecalibreerd op basis van de formatie van het Isthmus van Panama. Hoewel niet alle evolutionaire relaties achterhaald konden worden, zijn de nieuwe data over de diversiteit en evolutie van pteropoden een belangrijke eerste stap voor hun gebruik als bio-indicatoren van de voortschrijdende effecten van oceanverzuring. Om de evolutionaire stamboom van pteropoden verder op te lossen, moeten vooral meer soorten pseudotheicosomen en gymnosomen worden toegevoegd.

WELKE SOORTEN PTEROPODEN, HETEROPODEN EN HYPERIIDEN BEVINDEN ZICH WAAR IN DE ATLANTISCHE OCEAAN?

Over de verspreiding en abundantie van veel soorten marien zoöplankton is nog weinig bekend. Grote collecties meso- en macrozoöplankton, verzameld langs een transect in de Atlantische Oceaan tussen 46° noorderbreedte (NB) en 46° zuiderbreedte (ZB) en tot 300 meter diep, hebben bijgedragen aan het karakteriseren van de diversiteit en verspreiding van pteropoden, heteropoden en hyperiide amfipoden (Hoofdstukken 6 en 7). De soortenrijkdom van pteropoden en heteropoden was het grootst in de gestratificeerde (sub)tropische wateren tussen ongeveer 30° NB en 30° ZB, een diversiteitspatroon vergelijkbaar met wat bekend is van andere planktonische groepen (zoals decapoden, ostracoden en foraminiferen) (Hoofdstuk 6). De diversiteit van pteropoden en heteropoden was het laagst ten zuiden van 40° ZB. Het maximum aantal soorten en genera van hyperiiden is gevonden rondom de evenaar tussen 7° NB en 8° ZB langs een vergelijkbaar transect (Hoofdstuk 7). Deze hoge biodiversiteit rondom de evenaar suggereert dat de mechanismen die de soortenrijkdom in hyperiiden reguleren anders zijn dan van de meeste andere zoöplanktongroepen die een hoge diversiteit vertonen over een veel bredere tropische en subtropische zone. Diversiteitspatronen van hyperiiden worden waarschijnlijk beïnvloed door de verspreiding en diversiteit van de gastheersoorten in het plankton waarvan veel hyperiiden afhankelijk zijn. De verspreidingspatronen van gemeenschappen van pteropoden, heteropoden en hyperiiden kwamen grotendeels overeen met Longhurst's biogeochemische provincies. Een herhaalde

zoöplanktonbemonstering in combinatie met omgevingsdata, verzameld langs vergelijkbare transecten, is noodzakelijk om veranderingen in soortendiversiteits- en verspreidingspatronen als gevolg van oceaanverandering te meten.

TOEKOMSTIG ONDERZOEK

Een gecombineerde taxonomische aanpak biedt een steviger basis voor het onderscheiden van soorten dan identificaties die alleen op morfologie of DNA barcoding gebaseerd zijn. Door integratie van de verschillende benaderingen kunnen diverse en soms incomplete kenmerken gecombineerd worden om tot een goede identificatie te komen (Hoofdstuk 8). In toekomstig onderzoek kunnen nieuwe onderzoeksmethoden, ondanks hun tekortkomingen, de identificatie van soorten verder bevorderen en zo leiden tot een beter begrip van de evolutie van marien zoöplankton. Driedimensionale geometrisch morfometrische analyses onderscheiden waarschijnlijk beter tussen soorten dan de tweedimensionale geometrisch morfometrische analyses toegepast in dit proefschrift. Nauw verwante soorten kunnen met next-generation sequencing van het genoom beter worden onderscheiden dan met traditionele Sanger-sequencing van slechts een handvol genen. Metabarcoding, een methode gebaseerd op next-generation sequencing, kan bovendien onze kennis van zoöplanktongemeenschappen niet alleen in het bovenste deel van de oceaan vergroten, maar ook in de diepere oceaan waarover nog weinig bekend is. Daarnaast kunnen deze nieuwe methoden ook worden toegepast om langetermijnveranderingen in de soortensamenstelling van het zoöplankton als gevolg van bijvoorbeeld klimaatverandering te meten.

Alle gepubliceerde papers en data van dit proefschrift zijn gratis online beschikbaar en opgeslagen in de Dryad databank en GenBank.

Acknowledgements

First of all, I want to thank Katja Peijnenburg. Dear Katja, we first met during my BSc research project on pteropods at the University of Amsterdam in 2010. I also completed my first MSc project under your supervision in 2011, laying the foundations for the work that would result in this PhD thesis. As your very first PhD candidate I want to thank you for all your insights, positive conversations, all the times we visited conferences together, all the papers you stumbled upon that may somehow be interesting to cite in my own papers, and more than anything, your trust in me.

I thank my promotors Jef Huisman and Steph Menken from the Institute for Biodiversity and Ecosystem Dynamics at the University of Amsterdam for their advice and encouragement along the way.

I am grateful to members of the Naturalis Marine Biodiversity team and the former Marine Zoology department for the scientific discussions and not always equally scientific dinners. Dear Deborah Wall-Palmer, Remy van der Hulst, Marloes Tump and Serena Le Double, thank you for your great contributions to various papers. I enjoyed our collaboration. Dear Emma Otto, Diede Maas, Lisette Mekkes, Cas Retel, Aleksandra Dragozet, Thijs Bal, Renate Olie and Zoë van Kemenade, thank you for getting to know you. I also want to thank Willem Renema, Nicole de Voogd, Frank Wesselingh, Bert Hoeksema, Bastian Reijnen and Sancia van der Meij for their interest in my work. Although I often worked on this thesis from home, with one or two cats lying on my desk or on my lap, I thank Martien van Oijen for being my roommate at Naturalis.

I thank Erica Goetze from the University of Hawai'i at Mānoa for our collaboration, resulting in multiple publications. Dear Erica, I had a great time working with you and with Michelle Jungbluth during the Atlantic Meridional Transect 24 oceanographic expedition in 2014. I also thank all other scientists and crew members I met during this expedition.

Furthermore, I thank all members of my PhD committee for their interest in my work, all paper co-authors, all other colleagues at Naturalis and the Institute for Biodiversity and Ecosystem Dynamics whose valuable input helped me with different parts of this thesis, as well as all colleagues I met during my scientific outreach activities.

From a young age I have been interested in (marine) biology, long before I started my PhD project. With this in mind I am grateful to my biology teacher Yuri Robbers at the Stedelijk Gymnasium Leiden. I also thank Kjell Bjørklund for supervising my second MSc research project, for his recommendations, and for being a great mentor.

Continuous personal development and lifelong learning are very important to me. I thank my friends, family and acquaintances for their support. I especially thank my paranymphs Rebecca de Leeuw and Suzanne Veerman. A further list of names would be too extensive – you know who you are.

Last but not least: dear Mark Rog, words can't describe how happy I am with you in my life.

Curriculum vitae

'Curiouser and curiouser!' cried Alice

Alice's Adventures in Wonderland, Lewis Carroll, 1865

Born in The Netherlands with Dutch and British nationalities, Alice Karen BurrIDGE (July 16th, 1989) has always been a curious person. The subjects of her curiosity were diverse, but from an early age she could engage in what fascinated her for long stretches of time. Topics that fascinated her included astronomy, geology, history, garden life, cats, and the creatures hiding in the rocky shores of Devon. She was often found reading, writing stories, painting, or digging in the garden. After attending multiple primary and secondary schools she completed the Stedelijk Gymnasium in Leiden, The Netherlands, in 2007. Subjects included languages as well as sciences.

In 2007 she started her BSc studies in Earth Sciences at the University of Amsterdam. In her third year she pursued a minor in biological sciences, including paleoecology, aquatic ecology, and marine biology courses. Furthermore, she followed an elective course in relativity as well as courses in short story writing and impressionistic painting. Rather than choosing an earth science-focused individual research project to complete her BSc studies, she chose a project that would eventually get out of hand. Supervised by Dr. Katja Peijnenburg, she studied shell shapes of a group of pteropod snails (sea butterflies). She obtained her BSc degree Cum Laude in 2010.

In the same year she started her MSc studies in Biological Sciences, track Limnology & Oceanography, at the University of Amsterdam to further accommodate her interest in marine life. Upon following an array of courses in freshwater and marine biology as well as an elective course in astronomy, she pursued two research projects for which she was awarded an early-career research grant from the Malacological Society of London and an Erasmus scholarship. In her first project she returned to studying sea butterflies and learned how to work with genetic data. As part of this project she participated in a short student research cruise, organized by the University of Hawai'i at Mānoa, to collect fresh samples off the Hawai'ian coast. She presented the results of this project during the Young Systematists' Forum in London, earning the Best Presentation Prize. For her second

project she moved to Oslo, Norway, for seven months to study the diversity of radiolarians, marine microplankton, supervised by Professor Emeritus Kjell Rasmus Bjørklund at the University of Oslo and its Natural History Museum. In 2012 she obtained her MSc degree Cum Laude.

In September 2012 she started her PhD research on the diversity and evolution of marine zooplankton at Naturalis Biodiversity Center and the University of Amsterdam, supervised by Dr. Katja Peijnenburg. As part of her research she joined the Atlantic Meridional Transect #24 oceanographic expedition from England to the Falkland Islands in 2014, for which she obtained grants from the Dutch Royal Academy of Sciences (KNAW) and the Royal Netherlands Institute for Sea Research (NIOZ). On board she was part of the 'Zooplankton team' led by Dr. Erica Goetze (University of Hawai'i at Mānoa). She presented her work at conferences in Galway (Ireland), Honolulu (USA), London, Cambridge, Plymouth (UK), and Bergen (Norway). She also was a teaching assistant at the University of Amsterdam and supervised BSc and MSc student projects. Outreach activities were the Naturalis Biodiversity Center colloquium committee, Science Talks in Naturalis to communicate science to the general public, and a blog about her research activities: 'Alice's adventures underwater'.

CHAPTER 2

A.K. Burridge, K.T.C.A. Peijnenburg, E. Michel, J.A. Todd and J.R. Young designed the study and A.W. Janssen provided methodological input. A.K. Burridge, C. Hörnlein, M. Hughes, S.L. Bush, R. Gasca and K.J. Osborn provided specimen photographs and A.W. Janssen provided illustrations of fossil species. A.K. Burridge, C. Hörnlein, M. Hughes, S.L. Bush and K. Osborn generated the DNA sequences. A.K. Burridge and F. Marlétaz performed the phylogenetic analyses. A.K. Burridge visualized the data. A.K. Burridge and K.T.C.A. Peijnenburg wrote the manuscript. C. Hörnlein, A.W. Janssen, M. Hughes, S.L. Bush, F. Marlétaz, R. Gasca, A.C. Pierrot-Bults, E. Michel, J.A. Todd, J.R. Young, K.J. Osborn, and S.B.J. Menken reviewed and edited the manuscript.

CHAPTER 3

A.K. Burridge and K.T.C.A. Peijnenburg designed the study. A.K. Burridge generated, analyzed and visualized the data. A.K. Burridge and N. Raes applied ecological niche modelling. A.K. Burridge and K.T.C.A. Peijnenburg wrote the manuscript. E. Goetze, N. Raes and J. Huisman reviewed and edited the manuscript.

CHAPTER 4

A.K. Burridge and K.T.C.A. Peijnenburg designed the study. A.K. Burridge generated, analyzed and visualized the data. A.K. Burridge and A.W. Janssen wrote the manuscript. K.T.C.A. Peijnenburg reviewed and edited the manuscript.

CHAPTER 5

A.K. Burridge and K.T.C.A. Peijnenburg designed the study. A.K. Burridge generated the geometric morphometric data and R. v/d Hulst generated the DNA sequences. A.K. Burridge analyzed and visualized the data and wrote the manuscript. R. v/d Hulst contributed to the Materials and Methods paragraph. K.T.C.A. Peijnenburg and E. Goetze reviewed and edited the manuscript.

CHAPTER 6

A.K. Burridge and K.T.C.A. Peijnenburg designed the study. A.K. Burridge, D. Wall-Palmer and S.L. Le Double generated the data. A.K. Burridge analyzed and visualized the data and wrote the manuscript. K.T.C.A. Peijnenburg, E. Goetze, D. Wall-Palmer and J. Huisman reviewed and edited the manuscript.

CHAPTER 7

K.T.C.A. Peijnenburg and R. Vonk designed the study. M. Tump generated the data. A.K. Burridge analyzed and visualized the data. A.K. Burridge, K.T.C.A. Peijnenburg, E. Goetze, R. Vonk and M. Tump wrote, reviewed and edited the manuscript.

'But I have too deeply enjoyed the voyage, not to recommend any naturalist, although he must not expect to be so fortunate in his companions as I have been, to take all chances, and to start, on travels by land if possible, if otherwise, on a long voyage. He may feel assured, he will meet with no difficulties or dangers, excepting in rare cases, nearly so bad as he beforehand anticipates. In a moral point of view, the effect ought to be, to teach him good-humoured patience, freedom from selfishness, the habit of acting for himself, and of making the best of every occurrence. In short, he ought to partake of the characteristic qualities of most sailors. Travelling ought also to teach him distrust; but at the same time he will discover, how many truly kind-hearted people there are, with whom he never before had, or ever again will have any further communication, who yet are ready to offer him the most disinterested assistance.'

Charles Darwin after the voyage of the Beagle, 1836. Published in *The Voyage of the Beagle* (first published in 1909, New York: P.E. Collier).
